By decreasing afterload, CO may improve after ACEI or ARB therapy, thus preserving or even enhancing RBF. If, however, starting ACEIs or ARB leads to a rapid decrease in systemic BP that is not followed by an increase in CO, worsening renal function may ensue. It is impossible to predict which event will occur. Therefore, ACEI or ARB therapy needs to be started with low doses, and careful monitoring of the BP and renal function should occur as dosages are increased. Renal function and BP should be checked before and 1 to 2 weeks after initiation or dose increase. Patients with risk factors such as preexisting renal insufficiency or concomitant treatment with NSAIDs or high-dose diuretics may require more frequent monitoring. Diuretics are not contraindicated, but the diuretic dosage may need to be reduced to avoid overly aggressive diuresis and the accompanying volume depletion and hypotension. The guidelines recommend caution when prescribing ACEIs/ARBs in patients who have low systolic BPs (80 mm Hg), increased SCr (>3 mg/dL), bilateral renal artery stenosis, or serum potassium >5.0 mEq/L.[1]

ACE inhibitors block angiotensin II production

Figure 14-7 Factors affecting renal blood flow. Glomerular filtration is optimal when adequate hydrostatic pressure is maintained in the glomerulus. Governing factors include the blood flow rate to the glomerulus and the balance of afferent and efferent arteriole dilation and constriction. ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal antiinflammatory drugs; PGE, prostaglandin E.

Use of β-Blockers in HFrEF

CASE 14-1, QUESTION 17: After 3 days of furosemide and an ACEI, A.J.'s PND has resolved, but he still has difficulty walking without SOB and fatigue. His lower extremity edema has been significantly reduced. His current BP is 145/90 mm Hg, his pulse is 82 bpm, and his weight has dropped to 73 kg after diuresis. Repeat laboratory measurements include the following results:

Na, 139 mEq/L
K, 4.3 mEq/L
Cl, 98 mEq/L
CO_2, 27 mEq/L
BUN, 27 mg/dL
SCr, 0.6 mg/dL

The medical team has decided to discharge A.J. soon. You recommend that A.J. should be started on a β-blocker before discharge. What is your rationale?

β-Blockers have been evaluated during randomized clinical trials in more than 20,000 patients with varying degrees of HFrEF. Five meta-analyses have arrived at the same conclusions: the use of three β-blockers (bisoprolol, metoprolol succinate, or carvedilol) is associated with a consistent 30% reduction in mortality and a 40% reduction in hospitalizations in patients with HF.[175–179]

The ACC/AHA guidelines recommend bisoprolol, metoprolol succinate, or carvedilol for all patients with HFrEF unless there is a contraindication to their use or the patient is unable to tolerate treatment with a β-blocker.[1,5,6] They should be a part of the primary treatment plan with an ACEI or ARB. Patients should receive a β-blocker to slow the rate of disease progression and reduce the risk of sudden death. Patients do not need to be taking high doses of ACEIs before being considered for treatment with a β-blocker. To the contrary, in patients taking a low dose of an ACEI, the addition of a β-blocker produces a greater reduction in symptoms and in the risk of death than an increase in the dose of an ACEI. β-Blockers should be initiated before discharge in the vast majority of patients hospitalized for HF.[180] Only those clinically unstable patients who are hospitalized in an intensive care unit, require IV positive inotropic support, have severe fluid overload or depletion, have symptomatic bradycardia or advanced heart block that is not treated with a pacemaker, or have a history of poorly controlled reactive airways disease, are not candidates for a β-blocker.[181]

Based on all these factors, there is no question that A.J. should be started on a β-blocker. Treatment with a β-blocker should be initiated at low doses, followed by gradual increments in dose every 2 weeks as tolerated by the patient. Transient bradycardia, hypotension, and fatigue are common during the first 24 to 48 hours when β-blockers are first started or during subsequent increases in dosage. Thus, patients should be monitored daily for changes in vital signs (pulse and BP) and symptoms during this up-titration period. Bradycardia, heart block, and hypotension can be asymptomatic and require no intervention other than instructing the patient not to arise too quickly from a lying position to avoid postural changes. If either of these complications is accompanied by dizziness, lightheadedness, or blurred vision, it may be necessary to reduce the dose of β-blocker, the ACEI, or both or to slow the up-titration. In patients in whom benefits are especially apparent, but bradycardia or heart block is a concern, insertion of a pacemaker should be considered.

Because initiation of β-blocker therapy can also cause fluid retention, β-blockers should only be started or uptitrated when the patient is euvolemic. Patients should be instructed to weigh themselves daily and to adjust concomitantly administered diuretics as appropriate. Diuretic doses should be decreased temporarily if patients become hypotensive or their BUN begins to rise. Planned increments in the dose of a β-blocker should be delayed until any side effects observed with lower doses are tolerable or absent.

METOPROLOL AND BISOPROLOL

CASE 14-1, QUESTION 18: Metoprolol succinate (12.5 mg) is prescribed for A.J. Is this a good choice of agent and starting dose? What other similar drugs have been used to treat HF?

Several clinical trials substantiate the clinical benefits of metoprolol, a relatively selective β_1-receptor blocker, in HF.[182–185] By blocking β_1 receptors in the myocardium, HR, contractility, and CO are reduced at rest and during exercise, without a compensatory increase in peripheral vascular resistance. The relative sparing of β_2-receptors in the peripheral vasculature and lungs reduces vasoconstrictive and bronchospastic complications.

The Metoprolol CR/XL Randomized Intervention Trial in Heart Failure (MERIT-HF) showed a 35% reduction in all-cause mortality with sustained-release metoprolol succinate.[185] In this trial, 3,991 patients, most of whom had NYHA class II or III HF, were randomly assigned to receive metoprolol succinate controlled-release/extended-release (CR/XL) or placebo. The starting dose of metoprolol was 12.5 to 25 mg/day, which was gradually increased every 2 weeks to the target dose of 200 mg/day. Conventional therapy with diuretics, ACEIs, and digoxin was continued. At the end of the trial, 64% of subjects assigned to the active drug had reached the target dose. Although the number of subjects was too small to detect a statistical difference, patients with severe (class IV) HF seemed to benefit as well. Up to 15% of subjects had clinical worsening of HF, even at low metoprolol doses.

Positive results have also been seen with another relatively β_1-selective drug, bisoprolol fumarate.[186,187] In the first Cardiac Insufficiency Bisoprolol Study (CIBIS I), 641 subjects with moderate to severe HF were randomly assigned to placebo or bisoprolol (starting dose, 1.25 mg/day; maximal dose, 5 mg/day) added to conventional therapy for an average of 23 months.[186] A statistically

---

significant reduction in HF-associated hospitalization with the active drug and an insignificant trend toward reduced mortality were noted. In the larger Second Cardiac Insufficiency Bisoprolol Study (CIBIS II), reduction in both hospitalization and mortality in the bisoprolol-treated group was significant.[187] A total of 2,647 patients were included in the second trial, and doses were increased to as high as 10 mg/day. The study was stopped prematurely because of a 34% reduction in total mortality with bisoprolol. As in the MERIT-HF study, the number of patients with severe (class IV) HF was inadequate to determine the value of β-blocker therapy in this population.

Two dosage forms of metoprolol are marketed: metoprolol succinate extended-release and metoprolol tartrate immediate-release. Only metoprolol succinate is approved for HF in the United States. It is indicated for patients with mild to moderate (NYHA class II or III) HFrEF. The starting dose of 12.5 mg of metoprolol succinate prescribed for A.J. is consistent with the clinical trials and manufacturer's labeling. If the initial dose is tolerated, the dose can be doubled to 25 mg daily for an additional 2 to 4 weeks. The final target dose is 200 mg daily either as 100 mg BID or 200 mg once daily.

When choosing among the various formulations of metoprolol, pharmacokinetic and bioavailability differences should be considered.[182,183] Metoprolol succinate is available as 25-, 50-, 100-, and 200-mg tablets. Each tablet is slowly released at a constant rate for 20 hours, and provides β-blockade for 24 hours. The extended-release formulation retains its release characteristics even if the scored tablet is divided in half, but it should not be crushed or chewed. Having the ability to split tablets is useful in the titration of metoprolol succinate when the goal is to reach target doses and sometimes patients require slower titrations.

Metoprolol has several metabolic routes of elimination that can affect dosing and drug interactions. The major routes of elimination are via α-hydroxylation, O-demethylation, and N-dealkylation.[182,183] A smaller portion is metabolized by cytochrome P-450 2D6 (CYP2D6), and drugs that inhibit metabolism of that isoenzyme may affect the drug's plasma levels. Approximately 10% of patients are poor metabolizers, resulting in higher drug plasma concentrations in these patients.

A.J. should be advised that the beneficial clinical response to metoprolol is usually delayed and may require 2 to 3 months to become apparent. Even if symptoms do not abate, long-term treatment should be maintained to reduce the risk of major clinical events. Abrupt withdrawal of treatment with a β-blocker can lead to clinical deterioration and should be avoided.[188]

Bisoprolol is FDA approved for treatment of HFrEF. Dosage size limitations, however, limit the clinical use of this drug. For example, the starting dose of bisoprolol is 1.25 mg/day, whereas the smallest commercially available dose in the United States is a 5-mg scored tablet. Attempting to break the tablet into quarters is not practical.

CARVEDILOL

Carvedilol is a β-blocker with some α blocking acivity.[189] It is also theorized to possess antioxidant effects, which can protect against loss of cardiac myocytes and scavenge oxygen free radicals that are thought to potentiate myocardial necrosis. The correlation of these findings with clinical outcome is unknown.

Two pivotal studies support the use of carvedilol. The first was the U.S. Carvedilol Heart Failure Study.[190–194] Subjects were almost equally divided between NYHA class II and III HF and all had an EF of 35% or less despite diuretics, digoxin, and an ACEI. Subjects were stratified based on the severity of their HF and then randomly assigned to receive either placebo or carvedilol. The maximal dose given was 50 mg twice daily. During an average of 6.5 months, the mortality rate in the placebo group was 7.8% compared with 3.2% in the active treatment group, a statistically significant 65% risk reduction. The patients treated with carvedilol also had fewer HF-related hospitalizations. The most common side effect with carvedilol was dizziness.

In the Australia/New Zealand Carvedilol Study, 415 patients with chronic, stable HF were randomly assigned to receive placebo or carvedilol.[195] Those with severe symptoms were excluded. Maintenance doses in subjects randomly assigned to receive carvedilol ranged from 6.25 to 25 mg twice daily with an average follow-up of 19 months. After 12 months, EF had increased by 5.3%, and heart size was reduced in the carvedilol group. No differences between groups were found in treadmill exercise time, change in NYHA classification, or HF symptom scores, however. Most (58% in both groups) had neither improvement nor worsening of symptoms. The frequency of episodes of worsening HF was similar in the two groups. Total deaths in the carvedilol group were less than the placebo group, but most of the difference in mortality was attributed to non-CV deaths. There were 68% fewer hospital admissions for HF in the carvedilol group than for the placebo group. Overall, these findings could be interpreted as evidence for safety with either no overall benefit or a modest improvement with carvedilol.

The starting dose of carvedilol is 3.125 mg twice daily, with a doubling of the dose every 2 weeks or as tolerated up to a maximum of 25 mg twice daily in patients weighing less than 85 kg and 50 mg twice daily in larger patients. Hypotension, bradycardia, fluid retention, and worsening HF symptoms can occur in the first few weeks of therapy, necessitating additional diuretics, a reduction in dose, or discontinuation of carvedilol. Taking carvedilol with food slows the rate of absorption and reduces the incidence of orthostatic hypotension, which occurs in up to 10% of patients taking the drug. As with any β-blocker, carvedilol is not recommended for use in patients with asthma or poorly controlled diabetes.

Because carvedilol is metabolized by the CYP2D6 enzyme system, several potential drug interactions should be considered.[189,196] The best-documented ones are inhibition of metabolism by cimetidine and decreased carvedilol serum concentrations when taken with rifampin. Known inhibitors of CYP2D6 (quinidine, fluoxetine, paroxetine, and propafenone) might increase the risk of toxicity (especially hypotension). Carvedilol has been reported to increase serum digoxin levels by 15% by an unknown mechanism. Other sources of intrasubject variability in carvedilol response may be caused by differences in the extent or rate or absorption, stereospecific metabolism of the two isomers of the drug (carvedilol is a racemic mixture of S[–] and R[+] isomers), and impaired metabolism in the 10% of the population who lack CYP2D6 activity.[196]

CHOICE OF β-BLOCKER: METOPROLOL VERSUS CARVEDILOL

CASE 14-1, QUESTION 19: Would carvedilol be a better alternative than metoprolol for A.J.? What would be an appropriate dose and dosing schedule?

No consensus exists regarding the relative superiority of one β-blocker versus another. The additional α_1-blockade and antioxidant properties of carvedilol provide a theoretical basis for selecting carvedilol instead of metoprolol succinate or bisoprolol.

The Carvedilol or Metoprolol European Trial (COMET) was a multicenter, double-blind trial, where 3,029 patients with NYHA class II through IV HF and EF less than 35% were randomly assigned to receive either carvedilol (target dose, 25 mg BID) or metoprolol tartrate (target dose, 50 mg BID). Diuretics and ACEIs were continued in all subjects if tolerated. All-cause mortality was 34% for carvedilol compared with 40% with metoprolol ($p = 0.0017$).[197] The composite end point of mortality or all-cause hospital admissions was not significantly different. One major criticism of this study was the use of metoprolol tartrate instead of metoprolol succinate. Comparable doses between the two study groups have been questioned because the target dose of carvedilol was 25 mg twice daily compared with the target dose of metoprolol tartrate being 50 mg twice daily. Also, the trial used resting HR to determine comparable β-blockade among study groups rather than HR response to exercise. Exercise-induced HR changes are considered a better indicator of β-blockade.

Side effects and patient tolerability are similar among β-blockers in most trials. One investigator observed that carvedilol caused more hypotension and dizziness than metoprolol or bisoprolol, possibly owing to α_1-blockade or more rapid absorption.[198] Thus, metoprolol or bisoprolol may be preferred in patients with hypotension or with complaints of dizziness. Conversely, carvedilol may be preferred in patients with inadequately controlled HTN.

Whether carvedilol is a better choice for A.J. cannot be definitely answered. A starting dosage of 3.125 mg twice daily of carvedilol could be used in place of metoprolol succinate. Both drugs are generic, although the metoprolol sustained-release product is more expensive. A.J.'s provider decided to continue metoprolol and reserve use of carvedilol if he has difficulty tolerating metoprolol.

β-Blockers in Severe Heart Failure

CASE 14-1, QUESTION 20: The original clinical trials of β-blockers excluded patients with severe (NYHA class IV) HF at the time of randomization. For this reason, the FDA limited the original approval of carvedilol for use in NYHA class II and III HF. Likewise, the ACC/AHA guidelines strongly support the use of β-blockers in NYHA class II and III HF, but are less definitive about severe HF. If A.J. presented with NYHA class IV HF, what evidence supports or refutes the use of β-blockers in A.J.?

The COPERNICUS[199] study demonstrated clear benefit of carvedilol in patients with severe HF. COPERNICUS was a double-blind, placebo-controlled trial assessing the clinical benefits and risks of carvedilol in patients with advanced HF (NYHA class IIIB or IV).[199] Subjects were excluded who required intensive care, had significant fluid retention, were hypotensive, had evidence of renal insufficiency, or were receiving IV vasodilators or positive inotropic drugs. The starting dose of carvedilol was 3.125 mg twice daily, and increased every 2 weeks to a target dose of 25 mg twice daily. Of those in the carvedilol group, 65% achieved the target dose, with the mean dose being 37 mg at the end of the first 4 months of the trial. The trial was discontinued prematurely after an average patient follow-up of 10.4 months because of a significant survival benefit from carvedilol.

The BEST Investigators failed to demonstrate that bucindolol, a nonselective β-blocker with vasodilator properties, improved overall survival in patients with NYHA class III and IV HF.[200] They randomly assigned 2,708 patients to receive either bucindolol or placebo. Although the active drug yielded a significant decrease in NE levels and improvement in LV function, the study was stopped prematurely because of the low probability of showing any significant CV mortality benefit compared with placebo. A possible explanation is that bucindolol has intrinsic sympathomimetic activity that may counteract some of the benefits of β-blockade. Moreover, subgroup analysis suggested that black patients might have fared worse with bucindolol, raising concerns that β-blockers may not be effective therapy for black patients with advanced HF (see Case 14-3, Question 2, for further discussion of possible racial differences in drug response). Bucindolol has not been approved by the FDA.

Controversy still remains about the safe and effective use of β-blockers in class IV HF. There are data to support the safe and effective use of carvedilol. Clinically, the use of β-blockers is generally continued unless the patient requires inotropic therapy or if a dose increase of the β-blockers caused the ADHF episode. If the dose titration resulted in ADHF, then most patients should receive their previous β-blocker dose, but some may require acutely holding the β-blockers and reinitiating once stabilized.

Aldosterone Antagonists

CASE 14-2

QUESTION 1: B.D. is a 65-year-old Caucasian man with an LVEF of less than 25% who presents to the HF clinic today for follow-up of his recent HF hospitalization. His BP is 120/85 mm Hg and his pulse is 70 bpm. His current medications include lisinopril 10 mg daily, metoprolol succinate 150 mg daily, and furosemide 20 mg daily. You have reviewed his chart and noted that these are the maximal tolerated doses of lisinopril and metoprolol owing to dizziness and near syncope with higher doses. Today his laboratory results show that his SCr is 0.9 mg/dL and his potassium level is 3.5 mEq/L. Is this patient a candidate for aldosterone antagonist therapy?

Aldosterone contributes to HF through the increased retention of sodium and water and contributes to the depletion of potassium. Likewise, the diuretic and potassium-sparing actions of spironolactone are attributed to inhibition of aldosterone.[201] At one time, it was believed that optimal doses of ACEIs fully suppressed the production of aldosterone. It is now recognized that aldosterone levels can remain elevated through a combination of nonadrenal production and reduced hepatic clearance. In addition, it has become clear that both angiotensin II and aldosterone have other negative effects on the CV system, including myocardial and vascular fibrosis, direct vascular damage, endothelial dysfunction, oxidative stress, and prevention of NE uptake by the myocardium.[23,202] This led the RALES investigators to test the hypothesis that low doses of spironolactone might impart a cardioprotective effect in patients with severe HF independent of diuresis or potassium retention. In this trial, 1,663 patients with a history of NYHA class IV HF were randomly assigned to receive either spironolactone 25 mg or placebo. The dose of spironolactone could be increased to 50 mg if HF worsened without evidence of hyperkalemia.

The study was discontinued prematurely after a mean follow-up of 24 months when a significant reduction in mortality was observed in the spironolactone group. Hospitalization rates were lower in the patients treated with spironolactone. Hyperkalemia developed in 2% of the patients on spironolactone and 1% of those on placebo. Gynecomastia was reported in 10% of men treated with spironolactone compared with only 1% of those receiving placebo.

Subsequently, the aldosterone receptor antagonist eplerenone was studied in 6,632 patients with LV dysfunction after MI. In the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS), subjects were randomly assigned to receive either eplerenone or placebo.[65] Concurrent therapy included diuretics, ACEIs, β-blockers, and aspirin. During a mean follow-up of 16 months, there were 478 deaths (14.4%) in the eplerenone group compared with 554 deaths (16.7%) with placebo ($p = 0.008$). Most deaths were attributable to CV causes. More subjects experienced hyperkalemia with eplerenone than with placebo. Because eplerenone does not block progesterone and androgen receptors, gynecomastia and sexual dysfunction may be less.[65,202]

In 2011, the Eplerenone in Mild Patients Hospitalization and Survival Study in Heart Failure (EMPHASIS-HF) study was

---

published. This study evaluated eplerenone in patients with NYHA class II HF and an EF of less than 35%.[203] In EMPHASIS-HF, subjects were randomly assigned to receive either eplerenone or placebo. The primary outcome of the trial was CV death or HF hospitalization. During a median follow-up of 21 months, 18.3% of eplerenone-treated patients versus 25.9% of placebo patients had a primary outcome event ($p < 0.001$). This study further supported the role of aldosterone antagonists in HFrEF and expanded the known effectiveness to NYHA class II HF patients.

B.D. has NYHA class II HF based on his current symptom control and fits the profile of the subjects in the EMPHASIS-HF study, although he is on a low dose of ACEI. Starting B.D. on an aldosterone antagonist is appropriate because of his relative intolerance to increasing the dose of ACEI and β-blocker. An initial spironolactone dose of 25 mg per day should be chosen for B.D. based on the dose studied in the RALES trial. Spironolactone is chosen based on the likely class effects of aldosterone antagonists in HF treatment and the lower cost compared with eplerenone. This dose is safe based on his current potassium of 3.5 mEq/L and SCr of 0.9 mg/dL. He will need to be followed to determine whether a larger dose of spironolactone will be tolerated and safe after a measurement of his potassium and SCr 2 weeks after initiation. Specific monitoring parameters for the management of hyperkalemia in patients treated with aldosterone antagonists can be found in Table 14-11.

Digitalis Glycosides

CASE 14-2, QUESTION 2: B.D. has tolerated spironolactone 25 mg daily for 2 months. His laboratory test results today show that his potassium is 4.4 mEq/L and his SCr is 1.0 mg/dL. His BP is 124/82 mm Hg and his pulse is 70 bpm. He has come to the clinic today for a follow-up appointment with his cardiologist who notes that B.D. has had four HF hospitalizations in the last year. B.D. also reports increased SOB, DOE, and PND, although his weight is stable and he takes all his medications as prescribed. The medical resident who is also staffing the clinic asks whether it would be appropriate to add digoxin to B.D.'s medical treatment of HF. He was told by a colleague that in clinical trials digoxin reduced both HF symptoms and hospitalizations for HF. What would you recommend?

Debates raged for years about whether digitalis glycosides or vasodilators should be the drug(s) of first choice for treating HFrEF. By the time the first ACC/AHA guidelines were published, a clear consensus was evident. Vasodilators are first-line therapy, with digoxin being added for patients with supraventricular arrhythmias, failure to achieve symptomatic relief with vasodilators alone, or intolerable side effects from vasodilators. ACEIs are preferred compared with other vasodilators because of proven efficacy, convenience of dosing, and fewer side effects. By 1999, experts also recommended starting β-blocker therapy earlier in the treatment plan. Digoxin, however, continues to be widely debated.

CONTROVERSY ABOUT EFFICACY OF DIGOXIN

Correction of the underlying defect is a rational approach to the treatment of any disease. When considering HF solely as "pump failure" with a weakened myocardial muscle, then digitalis is the logical choice to improve cardiac contractility, CO, and renal perfusion. If focusing on symptom relief and increased exercise tolerance as markers of benefit, digoxin is effective. Critics, however, raised concerns that symptom relief was less in patients with normal sinus rhythm than in those with supraventricular arrhythmias. The most vocal critics claimed that the risk of digitalis toxicity did not warrant using this class of drugs in patients with normal sinus rhythm.

Using multivariate analysis, one group of investigators concluded that a third heart sound (S_3 gallop rhythm), an enlarged heart, and a low EF best predict those patients with normal sinus rhythm who will derive a beneficial response from digoxin.[204] Several other meta-analyses and critical reviews of the literature concurred that digoxin therapy provides a beneficial effect, especially in patients with severe symptomatic ventricular systolic dysfunction.[205,206] However these opinions were based on historical data and when many current therapies were not available.

DIGOXIN WITHDRAWAL TRIALS

In 1993, two digoxin withdrawal trials, PROVED[207] and RADIANCE,[208] were published. Both attempted to determine whether patients with HF who were already treated with digoxin would show deterioration after discontinuation. In both studies, patients had documented HFrEF (LVEF <35%), mild to moderate symptoms, were in normal sinus rhythm and stable for at least 3 months with treatment of a diuretic and digoxin (baseline digoxin level, 0.9–2.0 ng/mL). Patients in the RADIANCE trial were also stabilized on an ACEI in addition to the diuretic and digoxin.[207] A 12-week, double-blind, placebo-controlled treatment period followed initial stabilization in both studies. Patients in the active treatment groups continued digoxin at their previous dose. Those in the placebo groups were withdrawn from digoxin and given placebo.

In PROVED,[207] 42 subjects continued digoxin and 46 were given placebo. There were 29% treatment failures in the withdrawal group compared with 19% in those taking digoxin. Exercise tolerance worsened in more patients taking placebo. Those taking digoxin tended to maintain lower body weight and HR as well as higher EF. In the RADIANCE study, 85 subjects continued digoxin therapy and 93 were switched to placebo.[208] During the 12-week follow-up period, 4.7% of the subjects taking digoxin experienced worsening symptoms compared with 24.7% of the placebo-treated patients. More of the placebo-treated patients had worsening of EF and lower quality-of-life scores. When comparing the two trials directly, fewer patients deteriorated in both arms in the RADIANCE study. Whether this is attributed to a greater benefit from combining an ACEI with a diuretic compared with using a diuretic alone (as in PROVED) cannot be established.

These studies establish a beneficial effect of digoxin, even in those patients receiving concurrent ACEIs. At least two factors, however, limit extrapolation to all patients with HF. First, the investigators only assessed the value of therapy indirectly by using a withdrawal design instead of initiating therapy in patients previously untreated with digoxin. Second, the patients had advanced disease as evidenced by NYHA class II or III symptoms despite triple-drug therapy. Thus, the benefit of digoxin as initial monotherapy in early disease remains an unanswered question.

EFFECT OF DIGOXIN ON MORTALITY

The seminal study to answer the question of whether treatment with digoxin improves survival in HF was the Digitalis Intervention Group (DIG) study.[209] In this study, 6,800 patients with HF were randomly assigned to receive either digoxin or placebo. Eligibility requirements included an EF of 45% or less (mean, 28% in both groups), normal sinus rhythm, and clinical evidence of HF. Most subjects were in NYHA class II or III HF, although a small number of class I and class IV subjects were included. Concurrent therapies included diuretics, ACEIs, and nitrates. In both groups, 44% were taking digoxin before randomization. The starting digoxin dose (or placebo) was based on age, weight, and

---

renal function, with subsequent adjustments made according to plasma level measurements. Approximately 70% of subjects in both groups ended up taking 0.25 mg/day. By 1 month, 88.3% of patients receiving digoxin had serum levels between 0.5 and 2.0 ng/mL, with a mean of 0.88 ng/mL. Patients were followed for an average of 37 months.

For the primary outcome of total mortality from any cause, 34.8% of patients on digoxin and 35.1% of those on placebo died; corresponding CV deaths were 29.9% and 29.5%, respectively. Although neither of these differences is statistically significant, a trend was seen toward fewer HF-associated deaths and statistically fewer hospitalizations (risk ratio, 0.72) with digoxin. As would be expected, cases of suspected digoxin toxicity were greater in the active treatment group (11.9% vs. 7.9%), but the incidence of true toxicity was low.

The DIG trial improves on the PROVED and RADIANCE trials because it added digoxin to other therapy as opposed to being a withdrawal study and also because of the larger population. However, because nearly all patients were receiving concurrent vasodilator therapy, the value of digoxin as monotherapy on mortality rates remains unanswered.

The ACC/AHA guidelines indicate that patients with HF are unlikely to benefit from the addition of digoxin in stage A or stage B HF. In stage C patients, despite receiving optimal doses of ACEIs or β-blockers, digoxin may be beneficial to reduce HF hospitalizations.

Digoxin is prescribed frequently in patients with HF and concurrent AF, but β-blockers may be more effective in controlling the ventricular response, especially during exercise. Digoxin should be avoided if the patient has significant sinus or AV block, unless the block is treated with a permanent pacemaker. Digoxin should be used cautiously in patients taking other drugs that can depress sinus or AV nodal function (amiodarone or β-blockers), although patients usually will tolerate this combination.

Despite being on maximal tolerated doses of lisinopril and metoprolol, B.D. continues to have HF symptoms. In patients with persistent HF symptoms, especially like B.D. who also presents with an EF less than 25%, digoxin can be used as an additional agent. However, digoxin is not indicated as primary therapy for stabilization of patients with acutely decompensated HF. Such patients should first receive appropriate treatment, including IV medications.

SEX DIFFERENCES IN RESPONSE TO DIGOXIN

CASE 14-2, QUESTION 3: If B.D. had been a woman, would it have made any difference in the consideration to prescribe digoxin?

The retrospective post hoc analysis of the DIG study data reported that the death rate was lower among women in the placebo group as compared to men (28.9% vs. 36.9%; $p < 0.001$); however, this difference was not significant between women and men taking digoxin.[206] Women taking digoxin had a higher death rate than women taking placebo (33.1% vs. 28.9%), whereas death rates in men were similar in both groups. The authors speculate that a possible mechanism for the increased risk of death among women taking digoxin is an interaction between hormone-replacement therapy and digoxin. Progesterone might increase serum digoxin levels by inhibiting P-glycoprotein (PGP), thus reducing digoxin renal tubular excretion. Consistent with this hypothesis, digoxin serum concentrations after 1 month of therapy were higher in women than in men. The study investigators, however, did not gather data on estrogen and hormone-replacement therapy or consistently measure serum digoxin levels later in the trial. However, subsequent reanalysis[210] of the DIG data found lower serum concentrations (0.5–0.9 ng/mL) of digoxin associated with a decreased risk of hospitalizations and mortality in women. Serum concentrations greater than 1.2 ng/mL were associated with higher risk of death when compared with the placebo group. Higher digoxin concentrations resulted in worse clinical outcomes both in men and in women. Another analysis of patients treated with digoxin in the SOLVD trial failed to demonstrate a survival difference based on gender.[211] The available data suggest that serum digoxin concentrations in the range of 0.5 to 0.9 ng/mL are safe, improve LVEF, hemodynamics, and reduce hospitalizations irrespective of gender.

MAINTENANCE DOSE

CASE 14-2, QUESTION 4: What is the appropriate maintenance dose of digoxin for B.D.?

The usual maintenance doses of digoxin have traditionally ranged from 0.125 to 0.25 mg/day. With the increased emphasis on targeting lower serum concentrations (0.5–0.9 ng/mL), more patients are now empirically started at 0.125 mg/day. It is safer to start with a conservative dose and assess his needs after 1 to 2 weeks.

In all cases, smaller doses of digoxin are given to patients with impaired excretion rates (those with renal failure, older patients) or small-framed individuals. For example, a totally anuric patient may receive only 0.0625 mg 3 or 4 days/week.

Loading doses of digoxin are rarely necessary. Slow initiation of therapy with maintenance doses of digoxin is the method of choice for ambulatory or nonacutely ill patients with normal renal function. Even in the acute-care setting, no indication exists for loading doses of digoxin for HF alone. The exception might be if the patient has AF and it is desired to control ventricular response as quickly as possible. Even then, alternative drugs are likely to be used (see Chapter 15, Cardiac Arrhythmias).

MONITORING PARAMETERS

CASE 14-2, QUESTION 5: How should B.D.'s digitalis therapy be monitored? How useful are digoxin serum levels in monitoring therapy?

No clear therapeutic end point exists for digoxin therapy. Nonspecific electrocardiographic (ECG) changes (ST depression, T-wave abnormalities, and shortening of the QT interval) correlate poorly with both toxic and therapeutic effects of the drug.[212,213] Although digoxin serum levels are readily available from most clinical laboratories, no "therapeutic level" and corresponding "toxic level" are clearly defined.

A few patients, especially if they are hypokalemic or hypomagnesemic, will manifest apparent signs of toxicity when serum digoxin concentrations are less than 1 ng/mL. At the other extreme, some patients tolerate concentrations greater than 2 ng/mL with no signs of overt toxicity. Such overlap between therapeutic concentrations and toxic levels limits the value of serum level monitoring. Serum levels can be used as a guide in confirming suspected toxicity or in explaining a poor therapeutic response, but clinical evaluation ultimately remains the best therapeutic guide.

Clinical Evaluation

As with diuretic and vasodilator therapy, clinical monitoring is the key to evaluating adequacy of digitalis therapy. As B.D. begins to improve, he should have less dyspnea and complain less of PND, and a lower HR may be observed.

TREATMENT OF SUPRAVENTRICULAR ARRHYTHMIAS IN HEART FAILURE

CASE 14-2, QUESTION 6: B.D. did well for the next 6 months until he noted the onset of palpitations, which were diagnosed by ECG as AF. A month ago his primary care physician increased his digoxin dose to 0.25 mg every day. How should we treat his AF?

Supraventricular arrhythmias are frequently encountered in HF because volume or pressure overload can cause atrial distension and irritability. Specifically, AF is present in 10% to 30% of patients with advanced HF,[100] contributing to reduced exercise capacity, increased risk of pulmonary or systemic emboli, and worse long-term prognosis. Drug therapy should be aimed at controlling ventricular rate and preventing thromboembolic events. Cardioversion to normal sinus rhythm in patients with low EF and dilated cardiomyopathy is often unsuccessful.

Digoxin slows the ventricular response associated with AF and is a logical choice in patients with concurrent HFrEF. A potential limiting factor is that digoxin's AV-blocking properties are most evident at rest, and are less effective during exercise. Hence, digoxin may be ineffective at controlling exercise-induced tachycardia that limits the patient's functional capacity. β-Blockers are more effective than digoxin during exercise.[214–216] If digoxin, β-blockers, or both are ineffective, amiodarone is another useful alternative. Verapamil and diltiazem are not appropriate choices for rate control in patients with HFrEF due to their negative inotropic effects.

Some studies suggest that AF is an independent predictor of mortality in HF patients, and restoration of sinus rhythm may reduce mortality and prevent recurrences. Most patients who are electrically cardioverted revert to AF in a short time. In CHF-STAT (Congestive Heart Failure: Survival Trial of Antiarrhythmic Therapy),[217] a subset of patients who were converted to normal sinus rhythm with amiodarone treatment had significantly lower mortality than those who remained in AF. Similar results were observed in a substudy of the DIAMOND (Danish Investigations of Arrhythmia and Mortality on Dofetilide) trial,[218] in which HF patients with AF treated with dofetilide had significantly improved survival if the sinus rhythm was maintained. However, AF-CHF (Atrial Fibrillation in Congestive Heart Failure)[219] showed no mortality or morbidity benefits of rhythm control compared with rate control. The lack of mortality benefits seen in the AF-CHF might be explained by the high frequency of β-blocker use (88%). Antiarrhythmic agents are frequently unsuccessful in maintaining sinus rhythm.[220] Patients who benefit the most from conversion to sinus rhythm are the hemodynamically compromised. Maintaining sinus rhythm can potentially improve their quality of life.

The use of most antiarrhythmic agents, except amiodarone and dofetilide, is associated with worse prognosis due to proarrhythmic or negative inotropic effects and should be avoided in HF patients. Although amiodarone and dofetilide do not increase mortality in HF patients, they are associated with increased hospitalizations.[219] Current treatment guidelines do not support the routine use of anticoagulants in HF unless patients have concomitant AF or evidence of active thrombus. Finally, AV nodal ablation may be needed if tachycardia or bothersome symptoms persist despite aggressive pharmacologic intervention.

B.D. experienced AF while already taking a relatively high dose of digoxin (0.25 mg/day) and metoprolol. If his AF-associated palpitations persist, amiodarone should be started (see Chapter 15, Cardiac Arrhythmias). Amiodarone is a PGP inhibitor. The net effect of inhibition of gut PGP by amiodarone is increased bioavailability of digoxin. B.D.'s digoxin dose will need to be lowered by ~50% if amiodarone is started.[213,221] If digoxin is continued, serum levels should be closely monitored and patients observed for clinical evidence of toxicity.

DIGOXIN DRUG INTERACTIONS

CASE 14-2, QUESTION 7: What are other potential drug interactions with digoxin?

Two reviews of cardiac glycoside drug interactions have been compiled.[222,223] Since publication of these early reviews, a greater understanding of PGP-mediated drug interactions has evolved.[221,224] A brief summary of all digoxin interactions is found in Table 14-12. Drugs recently recognized as raising digoxin serum concentrations through PGP inhibition include atorvastatin.[225] CCBs (especially verapamil and diltiazem),[226] erythromycin and clarithromycin,[227,228] and cyclosporine. Conversely, rifampin[195] and St. John's wort[229] reduce oral digoxin bioavailability and serum concentrations via induction of intestinal PGP.

DIGITALIS TOXICITY

Signs and Symptoms

CASE 14-2, QUESTION 8: If B.D. presents with digoxin toxicity, what would be the common signs and symptoms of toxicity?

Digoxin has a narrow therapeutic index, and there is concern for morbidity and death associated with its use. The most important signs of digoxin toxicity are those relating to the heart. A common misperception is that gastrointestinal or other noncardiac signs will precede cardiac toxicity. To the contrary, cardiac symptoms precede noncardiac symptoms of digitalis toxicity in up to 47% of cases. Frequently nonspecific arrhythmias are the only manifestation of toxicity, with estimates that rhythm disturbances occur in 80% to 90% of all patients with digitalis toxicity.[230] Conversely, rhythm disturbances in patients taking digitalis are not always related to toxicity. In one study of 100 consecutive patients with suspected digitalis-induced arrhythmias, only 24 were confirmed as being toxic as defined by resolution of cardiac irritability after drug withdrawal. In the other 76 patients, the dysrhythmia persisted long after drug removal.[231]

Most arrhythmias can occur as a result of digoxin toxicity. Decreased conduction velocity through the AV node presents as a prolonged PR interval (first-degree AV block) and is seen in many patients with therapeutic concentrations of digoxin. However, higher concentrations of digoxin can impair conduction and result in bradycardia or a second-degree AV block. With severe toxicity, complete (third-degree) AV block can occur. AV block also may predispose patients to accelerated junctional rhythms. Increased automaticity of the atria can cause multifocal atrial tachycardia with block, paroxysmal atrial tachycardia with block, or AF.

Ventricular arrhythmias are among the most common rhythm disturbances caused by digoxin toxicity and include unifocal and multifocal premature ventricular contractions (PVCs), bigeminy, trigeminy, ventricular tachycardia, and ventricular fibrillation.[230,231] In the DIG trial, 11.9% of patients in the digoxin treatment group were found to have suspected digoxin toxicity compared with 7.9% in the placebo group. Comprehensive reviews are available on the topic of digitalis-induced arrhythmias.[213]

Hyperkalemia can develop as a consequence of massive digoxin ingestion by severely poisoning the Na^+/K^+ ATPase system, causing inhibition of the uptake of potassium by the myocardium, skeletal muscle, and liver cells.[232] The shift of potassium from inside to outside the cell can result in significant hyperkalemia, especially in patients with underlying renal insufficiency. These same patients also accumulate digoxin in the body because of decreased clearance of the drug.

Table 14-12

Digoxin Drug Interactions

Drug	Effect
Drugs Lowering Serum Digoxin Concentration	
Rifampin[195]	Probable induction of intestinal P-glycoprotein causing ↓bioavailability.
	↓Serum concentration after oral, but not IV digoxin. No change in digoxin renal clearance or half-life.
St. John's wort[229]	Possible induction of P-glycoprotein (33% reduction in digoxin trough concentrations).[316]
Sulfasalazine doses >2 g/day	Malabsorption of digoxin (decrease AUC of digoxin by 24%).[316]
Drugs Raising Serum Digoxin Concentration	
Amiodarone[213,221]	↑Serum digoxin levels inhibit intestinal P-glycoprotein (70% in 1 day).[316]
Atorvastatin[2,223]	20% increase in serum digoxin concentration with 80-mg dose, minimal effect with 20-mg dose. Speculated to inhibit intestinal P-glycoprotein, but not proven.
Calcium-channel blockers[213,221,226]	Inhibition of P-glycoprotein. Best documented with verapamil (70%–80%).[317] Diltiazem increases digoxin concentrations by 50% in some patients.[314]
Clarithromycin[227,316]	Inhibition of P-glycoprotein, decreased digoxin renal

	clearance. Digoxin clearance may be reduced by 60%, and plasma concentrations may increase by twofold.[316]
Cyclosporine[213,221]	Inhibition of P-glycoprotein, decreased digoxin renal clearance.
Erythromycin	↑Bioavailability in persons who normally metabolize digoxin in intestinal tract. May also inhibit P-glycoprotein in gut. Digoxin concentrations may increase by 100% in some cases.[316]
Itraconazole[318]	↑Serum digoxin levels by unknown mechanism. In one study, the AUC for digoxin was increased by 50% and renal elimination was decreased by 20%.[316]
Propafenone[213,319]	Inhibition of P-glycoprotein. Increases digoxin concentrations by 30%–60%.[316]
Quinidine[213,221,222,224,320–324] (usually doses above 500 mg/day may increase digoxin serum concentrations)	Inhibition of P-glycoprotein, decreased digoxin renal clearance, and increased bioavailability. Increases 25%–100% digoxin concentrations.[316]

References[213,221,223] include a discussion of many of these interactions that do not include a specific reference citation.
AUC, area under curve; IV, intravenous.

Vague gastrointestinal symptoms characteristic of digoxin toxicity are difficult to evaluate because anorexia and nausea are also part of clinical picture seen in patients with congestion.

CNS symptoms of digoxin are common, possibly associated with potassium depletion in neural tissue. Chronic digoxin intoxication can manifest as extreme fatigue, listlessness or psychic disturbances in the form of nightmares, agitation, and hallucinations.[233] Visual disturbances have been described as hazy vision and difficulties in both reading and red–green color perception. Other complaints included glitterings, dark or moving spots, photophobia, and yellow–green vision. Disturbances in color vision returned to normal 2 or 3 weeks after discontinuation of digitalis.

Digitalis-induced visual disturbances have been reported at serum concentrations below those considered to be toxic (all <1.5 ng/mL; range, 0.2–1.5 ng/mL).[234] Five of the reactions were described as photopsia (seeing lights not present in the environment), and one person had decreased visual acuity. The symptoms resolved in all but one subject when digoxin was discontinued.

Some prospective studies have shown a good correlation between serum digoxin serum concentration and toxicity,[233,235,236] whereas other investigators found a poor correlation.[237,238] Once levels exceed 6 ng/mL, the risk of mortality greatly increases.[239] Patients with hypokalemia can demonstrate digitalis toxicity at low serum digoxin concentrations.[240]

For many patients without life-threatening arrhythmias or major electrolyte imbalances, simple withdrawal of digoxin is the only treatment required. Potassium replacement should be considered in any patient with digoxin-induced ectopic beats who is hypokalemic. Digoxin-specific antibodies that bind digoxin molecules, rendering them unavailable for binding at receptors, are available.[241–246] The use of digoxin Fab products is restricted to potentially life-threatening intoxications (severe arrhythmias or hyperkalemia) that are either refractory to more conservative therapy or associated with extremely high serum digoxin concentrations.

Non–Angiotensin-Converting Enzyme Inhibitor Vasodilator Therapy

CASE 14-3

QUESTION 1: T.R. is a 57-year-old African American man (LVEF of 35%) who presents to the HF clinic for follow-up. His BP is 130/79 mm Hg and pulse is 65 bpm. Current medications include lisinopril 20 mg daily, metoprolol succinate 200 mg daily, spironolactone 25 mg daily, hydralazine 25 mg QID, and isosorbide dinitrate 20 mg TID. Why is the patient on hydralazine and isosorbide? What other forms of nitrates can be used in place of the isosorbide? Is combination therapy rational?

T.R. is treated with an ACEI, a β-blocker, and spironolactone. Despite this therapy, he is still having HF symptoms. He was started on hydralazine and isosorbide dinitrate, which is a possible next step in treating a patient with HFrEF.

Hydralazine's predominate action is as an arteriolar dilator. Decreasing afterload improves LV function. SVR is decreased, and this leads to an increase in CO.[140,247,248] Hydralazine is a direct-acting smooth muscle relaxant with significant arteriolar dilating effects in the kidneys and limbs. It has no effect on the venous system or on hepatic blood flow.

The reflex tachycardia and hypotension that accompany hydralazine in treating HTN are minimal or absent when treating HF. In patients with end-stage cardiomyopathy, significant hypotension can occur if the heart cannot respond appropriately by increasing CO. Because hydralazine is devoid of venous dilating properties, central venous pressure and pulmonary capillary wedge pressure (PCWP) are unchanged.[140,248]

The effect of a single dose of hydralazine occurs in about 30 minutes and lasts up to 6 hours. The average maintenance dose is 50 to 100 mg every 6 to 8 hours. T.R. is receiving an initial dose at this time and may warrant a higher dose in the future. Hydralazine used as monotherapy is not associated with long-term improvement in functional status.[248] Combination therapy of hydralazine with either nitrates or ACEIs is highly effective.

Although tachyphylaxis generally is not a significant problem with prolonged courses of hydralazine, some patients require increased diuretic doses to counteract hydralazine-induced fluid retention. This latter response reflects activation of the renin–angiotensin system after vasodilation of the renal vasculature. Other side effects with hydralazine include transient nausea, headache, flushing, tachycardia, and a lupus syndrome associated with prolonged, high doses (see Chapter 9, Essential Hypertension).

ORAL NITRATES

Nitrates have effects complementary to those of hydralazine.[140,247] They primarily dilate venous capacitance vessels. Venous dilation reduces preload, resulting in reductions in PCWP and right atrial pressure. They are especially effective in reducing the symptoms of pulmonary congestion. The lack of significant arterial dilation accounts for the observations that SVR is minimally reduced and CO remains unchanged.

Isosorbide

Because sublingual NTG has a short duration of action, more attention has been focused on isosorbide dinitrate. Sublingual isosorbide dinitrate is well absorbed and does not undergo first-pass metabolism. Its onset is rapid (5 minutes), but its effects are relatively short (1–3 hours). The usual starting dosage is 5 mg every 4 to 6 hours, but dosages may be titrated to 20 mg or more. Larger doses are associated with longer beneficial effects (approximately 3 hours), but also a high frequency of headaches and hypotension.

Oral isosorbide has a slower onset (15–30 minutes), but the duration of activity is longer (4–6 hours) than sublingual tablets. The smallest effective dose is 10 mg, with titration to dosages as high as 80 mg every 4 to 6 hours. The best dose for both sublingual and oral nitrates is that which provides the desired beneficial effect with the least side effects. Isosorbide mononitrate is frequently used as it is generally given once daily.

HYDRALAZINE–NITRATE COMBINATION

Combined afterload and preload reduction is clearly of benefit in improving symptoms and enhancing long-term survival. Compared with ACEIs, the hydralazine–isosorbide combination provides more improvement in exercise tolerance, but the side effect profile and survival statistics are better with ACEIs.[140] Generally, the use of the two drugs together is not accompanied by reflex tachycardia or hypotension.

Data supporting the use of combination hydralazine and nitrate vasodilator therapy come from two Veterans Administration Cooperative Studies (V-HeFT I and V-HeFT II).[70,140,247] These two studies confirmed symptomatic relief and improved exercise tolerance with combination therapy, and improved survival. (See Case 14-3, Question 2, for the discussion of the therapy in African American patients.)

In summary, nitrates alone are indicated for those patients with signs and symptoms of pulmonary and venous congestion. Use of an arterial dilator is beneficial in a patient with high SVR and low CO. Most patients, such as T.R., exhibit symptoms of decreased CO and elevated venous pressure, making combination therapy an attractive option. Although the hydralazine–isosorbide combination actually reduces symptoms slightly better than ACEIs, the data on survival are better with the ACEIs, probably owing to better adherence. A combination of an ACEI plus hydralazine, a nitrate, or both is common in patients with advanced disease.

Role of Race in the Pharmacotherapy of Heart Failure

CASE 14-3, QUESTION 2: Because T.R. is African American, would he be expected to respond differently to ACEIs or hydralazine–isosorbide dinitrate than a patient who is not African American?

In general, African American patients experience HF at an earlier age and are more likely to have HTN as a cause. The death rate of HF is higher for African American than for non–African American patients.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS AND HYDRALAZINE–ISOSORBIDE

Racial differences in response to drug therapy have been proposed, although this issue is far from resolved.[249–252] A post hoc analysis[250] of the V-HeFT trial data showed no difference in annual mortality between African American and non–African American patients receiving placebo. African American patients in the hydralazine–nitrate group had a significantly lower mortality rate than those in the placebo group. This implies that African American patients, but not non–African American patients, derive benefit from the treatment with hydralazine–isosorbide. These same investigators then reanalyzed the V-HeFT II trial results for possible racial differences between response to enalapril and the hydralazine–nitrate combination.[140,250] The outcome is difficult to interpret because of the absence of a placebo group. The all-cause annual mortality rate for African American patients was identical in the two drug groups (12.8% with enalapril and 12.9% with hydralazine–isosorbide). In non–African American patients, the corresponding mortality rates were 11% with enalapril and 14.9% with hydralazine–isosorbide. These data could be interpreted as either superior response to hydralazine–isosorbide in African Americans or inferior response to ACEIs in African Americans. The latter interpretation is consistent with the hypothesis that ACEIs might have a lesser BP-lowering effect in African American patients with HTN. A similar reanalysis of the SOLVD Prevention and Treatment trials,[136] which compared enalapril with placebo in patients with recent MI, concluded that enalapril is associated with a significant reduction in the risk for HF hospitalization among white patients (44% reduction) with LV dysfunction, but not among African American patients. Confounding variables contributing to all of these analyses include disproportionately low numbers of African American subjects in the trials, and possibly more underlying risk factors in African American subjects.

To address the effect of race on response to ACEIs, a meta-analysis of seven major ACEI studies with 14,752 patients, was conducted.[251]

The authors concluded that the relative risk for mortality when taking an ACEI compared with placebo was identical (0.89) for both African American and white patients. The authors urged that ACEIs not be withheld from African American patients. Although rare, there is a higher rate of angioedema with ACEIs in black patients compared to white patients.

The African American Heart Failure Trial (AHeFT) was a randomized comparison trial of hydralazine–isosorbide dinitrate versus placebo in African American patients with NYHA class III or IV HF who were receiving standard HF therapy (diuretics, β-blockers, ACEIs or ARB, digoxin, and aldosterone antagonists).[71] The primary end point was a composite of all-cause death, first hospitalization for HF, and quality of life scores at 6 months. Reduction in the primary end point events was statistically significant in favor of the active drug combination. All-cause mortality declined 43% with hydralazine–isosorbide dinitrate versus placebo ($p = 0.012$). The study also reported a 39% reduction in first hospitalization for HF with hydralazine–isosorbide dinitrate versus placebo ($p < 0.001$). The addition of hydralazine and isosorbide dinitrate is effective in African American patients with NYHA class III or IV HF already receiving ACEIs and β-blockers.[1] The results of AHeFT were also the primary factor leading the FDA to approve the combination product of hydralazine and isosorbide dinitrate (BiDil) for adjunctive treatment in self-identified African American patients. Using BiDil might improve compliance by using a combination tablet. Cost is lower using generic hydralazine and isosorbide as separate drugs.

β-BLOCKERS

A possible racial difference in response to β-blocker drugs has also been hypothesized based on effects observed in HTN.[249,251,252] A post hoc analysis of the U.S. Carvedilol Heart Failure trials[190–194] concluded that the benefit of carvedilol was similar in both black and nonblack patients.[252]

Contradictory evidence comes from BEST.[200] In this trial (discussed in Case 14-1 Question 20), 2,708 patients with NYHA class III or IV HF were randomly assigned to either bucindolol or placebo. Bucindolol is a nonselective β-blocker with partial agonist activity that imparts weak vasodilation. A unique characteristic of this study was a preplanned subgroup analysis for racial differences. Although there was a trend toward reductions in CV mortality and hospitalization with bucindolol, the trial was terminated after 2 years. A subgroup analysis showed a mortality benefit in nonblack subjects, but no benefit in black subjects. A meta-analysis of five major β-blocker in HF studies representing 12,727 patients has been conducted, suggesting that black patients will derive similar benefit from β-blockers as do white patients when given carvedilol, metoprolol, or bisoprolol.[251]

Critical Care Management of Heart Failure

CASE 14-4

QUESTION 1: L.M., a 62-year-old black man, was admitted several days ago with severe, progressive, and debilitating symptoms of HF. His family history is significant in that his father and two brothers died of heart attacks shortly after the age of 40. L.M. has a 5-year history of HF that is symptomatic despite treatment with furosemide 40 mg daily, lisinopril 10 mg daily, carvedilol 12.5 mg BID, digoxin 0.125 mg daily, and spironolactone 25 mg daily. His last echocardiogram showed an EF of 25%. He has a past medical history of HTN, CAD, and HF. During the last week, L.M.'s DOE became progressively worse, and he was confined to bed because of fatigue. He wakes once or twice nightly with PND. Physical examination revealed jugular venous distension, bilateral rales, hepatomegaly, and 3+ peripheral edema. Chest radiograph showed cardiomegaly and pulmonary congestion. His BP was 154/100 mm Hg and pulse was 105 bpm.

Laboratory test results include:

Serum Na, 134 mg/dL
K, 4.3 mg/dL
BUN, 15 mg/dL
SCr, 1.3 mg/dL
Glucose, 90 mg/dL
BNP, 944 pg/mL

Hemoglobin, hematocrit, troponin, and liver enzymes were within normal limits. L.M. was admitted to the hospital with ADHF. What factors are used to stratify risk for in-hospital mortality and morbidity?

ADHF is associated with high morbidity and mortality. It is the leading reason for hospitalizations among the elderly. Post discharge mortality among patients with HF is 11% at 30 days and 37% at 1 year.[253] The most common precipitants of HF hospitalization are noncompliance (dietary or medication), acute myocardial ischemia, uncontrolled comorbidities (HTN, diabetes mellitus, chronic kidney disease, arrhythmias), and prescribing of negative inotropic agents, NSAIDs, or other inappropriate agents. Regardless of the precipitating event, the common pathophysiologic state that perpetuates the progression of HF is complex. A cascade of hemodynamic and neurohormonal derangements provoke activation of adrenergic systems and RAAS, leading to volume overload and hypoperfusion—classic symptoms of ADHF. According to the ADHF National Registry, nearly half of the patients who present with ADHF have preserved EF (>50%).[254]

In-hospital mortality remains as high as 20% for patients who present with elevated BUN and creatinine, and low systolic BP (SCr >2.75 mg/dL, BUN >43 mg/dL, systolic BP <115 mm Hg[252]). Patients presenting with hyponatremia (serum sodium less than 135 mEq/L) have the worst outcomes and are more likely to receive inotropic agents. After discharge, patients who continue to be hyponatremic have an 8% risk of rehospitalization per 3 mEq/L decrease in serum sodium. Uric acid greater than 7 mg/dL in men and greater than 6 mg/dL in women is associated with a high admission rate for HF. Admission and discharge levels of BNP are also helpful in predicting rehospitalizations. According to studies, a 30% to 40% reduction in BNP levels during hospitalization may improve outcomes. Other biomarkers such as cardiac troponin levels, C-reactive protein, and apolipoprotein A-I levels are all linked to HF readmissions.[9] All these factors can be used to stratify risk for in-hospital mortality.

Another approach to risk stratification and therapeutic decision-making is based on hemodynamic profiles. Most patients with acute HF can be classified into one of four hemodynamic profiles using relatively simple assessment techniques (Fig. 14-8).[255–258] Patients are assessed for the presence or absence of elevated venous filling pressures ("wet" vs. "dry") and adequacy of vital organ perfusion ("warm" vs. "cold"). Elevated filling pressure can be assessed at the bedside by observing jugular venous distension, presence of a third heart sound (S_3), peripheral edema, and ascites. Presence or absence of rales on auscultation is not considered a reliable indicator.[258] Hypotension, weak peripheral pulse, a narrow pulse pressure, cool extremities, decreased mental alertness, and rising BUN and SCr are indicators of decreased organ perfusion. Continuous BP, ECG, urine output, and pulse oximetry measurements are standard noninvasive monitoring for all patients in an intensive care unit. Invasive hemodynamic monitoring is used in critically ill patients when more precise measurements of filling pressures, SVR, and CO or cardiac index are desired. The goals are to achieve a right atrial pressure of less

---

than 8 mm Hg, pulmonary artery pressure of less than 25/10 mm Hg, pulmonary artery wedge pressure of 12 to 16 mm Hg, SVR 900 to 1,400 dyne second/m^5, and a cardiac index greater than 2.5 L/minute/m^2. (See Chapter 17, Shock, for more detailed discussion of hemodynamic monitoring.)

CASE 14-4, QUESTION 2: From his clinical presentation, what is L.M.'s hemodynamic profile? What are therapeutic goals for L.M.?

L.M.'s DOE, rales, peripheral edema, PND, and jugular venous pressure are consistent with ADHF and volume overload. L.M. does not have signs of hypoperfusion. His hemodynamic profile is "warm and wet" (subset II, Fig. 14-8). According to the guidelines, a rapid diagnosis of ADHF is necessary to initiate appropriate treatment. In patients who have established HF, precipitating factors should be identified and addressed. At the time of discharge, medications that decrease morbidity and mortality in HF should be optimized. BNP levels should be considered when the diagnosis is uncertain can be helpful in differentiating between cardiac and noncardiac causes of dyspnea.

Because volume overload is central to the pathophysiology of most episodes of ADHF, the primary goal is to relieve congestion. However, diuretics should be cautiously used in subset IV to avoid decreases in PCW less than 15 mm Hg as this can compromise preload and further reduce CO. Despite diuretics being the main therapy in reducing volume overload, their routine use in ADHF is associated with worsening renal function and mortality. Mortality rates are higher in patients receiving chronic diuretic therapy compared with those not receiving diuretics. These findings are based on retrospective data. Nevertheless, they suggest an association between mortality and diuretic use in patients with ADHF. (See Case 14-1, Question 7, for diuretic dosing.)

ULTRAFILTRATION

Ultrafiltration is an alternative approach for treating hypervolemia. It involves the use of a small device to rapidly remove fluid (up to 500 mL/hour). Typically, ultrafiltration for HF is reserved for patients with renal failure or those unresponsive to diuretics. Studies[259,260] in ADHF patients have shown that peripheral venovenous ultrafiltration results in greater weight loss and fluid removal, and reduced hospital length of stay and hospital readmissions compared with medical therapy. Significant reductions in neurohormonal activation and no significant changes in SCr or electrolytes were reported with ultrafiltration.[261] The Ultrafiltration versus Intravenous Diuretics for Patients Hospitalized for Acute Decompensated Heart Failure (UNLOAD trial)[262] randomly assigned 200 patients to either ultrafiltration or aggressive IV diuretic therapy. The study showed ultrafiltration significantly improved weight loss at 48 hours (5.0 vs. 3.1 kg; $p < 0.001$), decreased the need for vasoactive drugs (3% vs. 13%; $p = 0.02$), and reduced 90-day hospital readmission (18% vs. 32%; $p = 0.02$) compared with diuretics alone. Ultrafiltration has a class IIb recommendation for patients with refractory HF not responsive to medical therapy. Patients with fluid overload and some degree of renal insufficiency and those refractory to diuretic therapy are candidates for ultrafiltration.[1]

Intravenous Vasodilators

CASE 14-4, QUESTION 3: L.M. received a 40-mg IV furosemide dose with no improvement in symptoms. Then he received an 80-mg IV dose with only marginal improvement. The decision is made to start nitroprusside. What is the role of IV vasodilator therapy in someone with ADHF?

The guidelines[1] recommend the addition of vasodilators in conjunction with diuretics to reduce congestion in patients with fluid overload. In the presence of asymptomatic hypotension, IV NTG, nitroprusside, or nesiritide may be considered cautiously in combination with diuretics. In the presence of low SVR, arterial vasodilators (e.g., nitroprusside, high-dose NTG, nesiritide) can further compromise perfusion and should be avoided, especially in patients who have preexisting hypotension.

NITROPRUSSIDE

Nitroprusside dilates both arterial and venous vessels, decreasing afterload and preload. Nitroprusside is valuable in severely congested patients with HTN or severe mitral valve regurgitation complicating LV dysfunction. Its major disadvantages include risk of hypotension, reflex tachycardia, "coronary steal" in CAD patients, and accumulation of toxic metabolites. Thiocyanate and cyanide toxicity are most likely seen in renal insufficiency and in patients who receive more than 4 mcg/kg/minute of nitroprusside for greater than 48 hours. When stopping nitroprusside therapy, a slow taper is recommended because a rebound increase in HF has been observed 10 to 30 minutes after drug withdrawal (see Chapter 16, Hypertensive Crises).

Nitroprusside must be given by continuous IV infusion, with arterial line placement and intensive care unit admission in most institutions. It is unstable if exposed to heat and light after reconstitution.

INTRAVENOUS NITROGLYCERIN

NTG primarily dilates the venous capacitance vessels with a slight effect on the arterial bed. Patients with acute MI and pulmonary edema are often considered ideal candidates for IV NTG. The resulting reduction in preload reduces PCWP. Because nitrates have minimal effect on afterload, CO will likely remain unchanged or increase slightly. In some patients, NTG could decrease CO if preload is reduced to less than 15 mm Hg. NTG is generally initiated at 10 mcg/minute and increased by increments of 10 to 20 mcg, until the patient's symptoms are improved or PCWP is less than 16 mm Hg. The most common side effect is headache, which can be treated with analgesics and often resolves after continuous therapy. Tachyphylaxis to NTG occurs within 24 hours after initiation of therapy. Approximately 20% of HF patients exhibit resistance to high doses of NTG.[1] Nitroprusside is a good choice for patients such as L.M. because he has elevated BP and no history of CAD.

NESIRITIDE

Nesiritide is recombinantly produced BNP.[31,32] BNP binds to guanylate cyclase receptors on vascular smooth muscle leading to expression of cyclic guanosine monophosphate and vasodilation. Other actions include inhibition of ACE, sympathetic outflow, and ET-1. Peripheral and coronary dilation coupled with improved RBF and increased glomerular filtration all contribute to the beneficial effects of nesiritide. Metabolic clearance of nesiritide is by a combination of binding to cell surfaces with cellular internalization and lysosomal proteolysis as well as proteolytic cleavage by endopeptidase. It undergoes minimal renal clearance. The elimination half-life is 8 to 22 minutes, necessitating a constant IV infusion.

In clinical trials of hospitalized patients with severe HF, nesiritide produced hemodynamic effects and reduction in dyspnea scores comparable to NTG when used in combination with IV diuretics and either dopamine or dobutamine.[31,32] Dose-dependent hypotension is the most common side effect with nesiritide, reported in 11% to 32% of patients. The incidence of PVC and nonsustained ventricular tachycardia is less with nesiritide than with dopamine, dobutamine, or milrinone. Nesiritide's side effects include headache, abdominal pain, nausea, anxiety, bradycardia, and leg cramps.

The use of nesiritide is generally restricted to those patients with acute HF exacerbations who are hypervolemic and have a PCWP greater than 18 mm Hg despite high doses of diuretics and IV NTG. In contrast to NTG, nesiritide has natriuretic properties that are additive to loop diuretics. It should be avoided in patients with a systolic BP less than 90 mg Hg or in cases of cardiogenic shock. Dobutamine or milrinone should be added or substituted in hypotensive patients or those with a cardiac index of less than 2.2 L/minute/m^2.

The IV infusion of nesiritide is prepared by diluting the contents of a 1.5-mg vial to 6 mcg/mL in 250 mL of 5% dextrose or 0.9% NaCl. An initial loading dose of 2 mcg/kg is sometimes given intravenously over 60 seconds, followed by a continuous IV infusion at a rate of 0.01 mcg/kg/minute. The desired response is a reduction of PCWP of 5 to 10 mm Hg at 15 minutes. The dose can be increased in 0.005 mcg/kg/minute increments at 3-hour intervals to a maximum of 0.03 mcg/kg/minute. Dosage should be titrated to a PCWP less than 18 mm Hg and a systolic BP greater than 90 mm Hg.

Although nesiritide is indicated in the treatment of ADHF, concerns were raised about its safety. A meta-analysis of randomized, controlled trials of nesiritide in ADHF suggests that nesiritide may be associated with worsening renal function and increased mortality.[263,264] The conclusions of the meta-analysis have been criticized, however. For example, the Vasodilation in the Management of Acute Congestive Heart Failure (VMAC) study was included in the meta-analysis but was not designed to evaluate renal end points, and therefore its inclusion may not be appropriate.[265] Differences in baseline characteristics of the treatment groups may have contributed to an increased risk of 30-day mortality seen in those patients treated with nesiritide.

The efficacy and safety of nesiritide have been evaluated in outpatients. The Follow-up Serial Infusions of Nesiritide (FUSION I) trial[266] included 202 patients with NYHA class III and IV who had been hospitalized for ADHF at least twice within the preceding year and once in the preceding month. Patients were randomly assigned to receive usual care with or without open-label nesiritide. A subgroup of patients was identified as high risk if they had at least four of the following: SCr greater than 2.0 mg/dL during the preceding month, NYHA class IV for the preceding 2 months, age greater than 65 years, history of sustained ventricular tachycardia, ischemic HF etiology, diabetes, or use of nesiritide or inotropic agents as outpatients within the preceding 6 months. These patients at high risk experienced fewer HF exacerbations and renal adverse effects with nesiritide infusions.

The benefit and safety in outpatients with severe HF was further explored in the Follow-Up Serial Infusions of Nesiritide for the Management of Patients With Heart Failure (FUSION II) trial.[267] This was a randomized, placebo-controlled, double-blind prospective trial of 911 subjects with advanced HF or chronic decompensated HF. Subjects were randomly assigned to receive a 2-mcg/kg nesiritide bolus followed by a 0.01-mcg/kg/minute infusion for 4 to 6 hours, or a matching placebo regimen, once or twice weekly for 12 weeks. Both groups also received optimal medical therapy and device therapy. Patients were required to have a creatinine clearance less than 60 mL/minute. No outpatient IV inotropic or vasodilator therapy was allowed. After 24 weeks, no difference was noted in the primary end point of either death or hospitalization for cardiac or renal causes. Significantly more drug-related adverse events (mainly hypotension) occurred in the nesiritide group (42.0%) compared with placebo (27.5%). The incidence of worsening renal function was significantly lower with nesiritide (32%) vs. placebo (39%).

The results of these studies alleviated some concerns regarding the safety of nesiritide; however, a group of independent cardiologists designed an “Acute Study of Clinical Effectiveness of Nesiritide in Decompensated Heart Failure” (ASCEND-HF)[268,269] trial to definitively answer the question of nesiritide safety and efficacy. This was a double-blind placebo trial, which enrolled 7,141 patients with ADHF. The participants were randomly assigned to receive an IV bolus (at the investigator’s discretion) of nesiritide 2 mcg/kg or placebo followed by continuous IV infusion of nesiritide 0.01 mcg/kg/minute or placebo for 7 days in addition to standard therapy. The co-primary end points were the rate of HF hospitalizations or all-cause mortality through day 30 and a significant improvement in self-assessed dyspnea at 6 or 24 hours. Compared with placebo, nesiritide did not reduce 30-day mortality or rehospitalization. Nesiritide improved dyspnea at 6 and 24 hours compared with placebo. Nesiritide did not worsen renal function. Proponents of nesiritide argue that even though the ASCEND-HF trial failed to show a major benefit, it is the only vasodilator that has been well studied. The controversy regarding the safety of nesiritide can be put to rest.

L.M. responded well to nitroprusside and needed no other therapy. However, IV NTG and IV nesiritide are alternatives to nitroprusside in patients with “wet and warm” acute HF. NTG or nesiritide can either be a substitute for nitroprusside or be combined with nitroprusside. At the time of discharge, furosemide therapy should be continued, although the dose should be titrated to prevent DOE and peripheral edema. The dose of lisinopril and carvedilol should also be titrated to target or tolerated doses.

Inotropic Agents

CASE 14-5

QUESTION 1: B.J. is a 60-year-old man who presents to the emergency department with worsening DOE. He reports increased SOB during the last week. His medical history includes HTN, CAD, hyperlipidemia, and HF (EF 25%). His medications include metoprolol succinate 100 mg daily, enalapril 5 mg twice daily, furosemide 40 mg BID, aspirin 81 mg daily, and lovastatin 20 mg at bedtime. His vital signs on admission include BP 100/75 mm Hg, HR 92 bpm, respiratory rate 18 breaths/minute, and O_2 saturation 94% on room air. Laboratory values were BUN 20 mg/dL and SCr 1.4 mg/dL. Physical examination reveals pulmonary and peripheral edema and JVP 10 cm. He is given 80 mg IV furosemide with minimal response. His dose was increased to 120 mg IV furosemide and he still does not respond adequately. Within the last 24 hours his SCr has increased to 1.8 mg/dL and his BP is 92/70 mm Hg. The decision is made to admit him to the coronary care unit where a pulmonary artery catheter (Swan–Ganz catheter) is placed, and the following hemodynamic variables are: PCWP 21 mm Hg; CO 3.64 L/min (cardiac index 1.8 L/minute/m^2); SVR 1,489 dyne·second/cm^5. Is B.J. a candidate for inotropic therapy?

DOPAMINE AND DOBUTAMINE

The hemodynamic profile of B.J. is category IV (cold and wet) because of hypoperfusion and congestion. According to the ACC/AHA guidelines,[1] IV inotropic agents (dobutamine, dopamine, milrinone) are indicated in symptomatic patients with reduced LVEF, low CO, or end-organ dysfunction (i.e., worsening renal function) and in patients who are intolerant to vasodilators. They are recommended for patients with cardiogenic shock or refractory symptoms, and may be used in patients requiring perioperative support after surgery or for those awaiting transplantation. Dobutamine is usually preferred in patients with low-output HF. Dobutamine improves CO, decreases PCWP, and decreases total SVR with little effect on HR or systemic arterial pressure when compared with dopamine.[270] (See Chapter 17, Shock, for further information on dopamine and dobutamine.)

PHOSPHODIESTERASE INHIBITORS: MILRINONE

Although β-agonists, such as dobutamine, have been traditionally used in patients with ADHF, the phosphodiesterase inhibitor milrinone is an alternative to the catecholamines and vasodilators for the short-term parenteral treatment of severe congestive failure. This agent selectively inhibits phosphodiesterase III, the cyclic adenosine monophosphate (cAMP)-specific cardiac phosphodiesterase. Enzyme inhibition results in increased cAMP levels in myocardial cells and enhances contractility. The activity is not blocked by β-blockers. Phosphodiesterase inhibitors are also vasodilators. It has been suggested that at low doses they act more as unloading agents rather than as inotropic agents; others refute this viewpoint. Their overall hemodynamic effect probably results from a combination of positive inotropic action plus preload and afterload reduction.

Milrinone is structurally and pharmacologically similar to inamrinone, which is no longer used.[271–273] Besides inhibiting phosphodiesterase, it also may increase calcium availability to myocardial muscle. It has both inotropic and vasodilating properties. HR increase and myocardial consumption may be less with milrinone than with dobutamine[274,275] The half-life of milrinone is 1.5 to 2.5 hours, with renal clearance accounting for approximately 80% to 90% of total body elimination and is prolonged in patients with renal dysfunction. Although a loading dose of 50 mcg/kg is in the product labeling, it is rarely given due to resulting hypotension. Maintenance infusions are typically between 0.2 and 0.75 mcg/kg/minute. The infusion is adjusted according to hemodynamic and clinical responses and should be decreased in patients with renal insufficiency. The primary concern with milrinone is ventricular arrhythmias, reported in up to 12% of patients. Supraventricular arrhythmias, hypotension, headache, and chest pain also have been reported. Thrombocytopenia is rare.

The Outcomes of a Prospective Trial of Intravenous Milrinone for Chronic Heart Failure (OPTIME-CHF) trial assessed the in-hospital management of 951 patients with acute HF exacerbation (mean LVEF 23%) but not in cardiogenic shock.[274,275] In addition to standard diuretic and ACEI therapy, subjects were randomly assigned to receive either milrinone or placebo. The initial milrinone infusion rate was 0.5 mcg/kg/minute with no loading dose. The primary end point was total numbers of days hospitalized for CV causes from the time of the start of study drug infusion to day 60. No difference was found between milrinone and placebo with mortality at 60 days (10.3% with milrinone and 8.9% with placebo).[274] Follow-up analysis categorized subjects as ischemic vs. nonischemic.[275] Within the cohort of patients with ischemia, milrinone-treated patients tended to have worse outcomes than those treated with placebo. In contrast, nonischemic patients had a trend toward better outcomes with milrinone than with placebo. From these data, it can be concluded that the benefits of milrinone in patients with acute exacerbations of HF are minimal and more likely to be seen in patients with a nonischemic etiology of HF. Worse outcomes may be seen in patients with ischemic HF. However, short-term infusions of milrinone were not associated with excess mortality.

Few trials have compared dobutamine to milrinone in ADHF. One small retrospective analysis evaluated 329 patients admitted for ADHF (EF of less than 20%) who either received IV dobutamine or milrinone.[276] Hemodynamic response, need for additional therapies, adverse effects, length of stay, and drug cost were evaluated. Patients were similar in clinical presentation, but the milrinone group had higher mean pulmonary arterial pressure. A greater percentage of patients received dobutamine (81.7%)

---

versus milrinone (18.3%.). Only 19% of patients were taking β-blockers before admission. Clinical outcomes were similar and there was no significant difference in the in-hospital mortality rate, adverse effects, ventilator use, or length of stay. More patients in the dobutamine group required nitroprusside to achieve optimal hemodynamic response. The study concluded that both drugs have comparable efficacy.

Other factors to consider when deciding which inotropic agent should be used in ADHF are renal function, BP, and concomitant β-blocker use. Milrinone has a longer half-life than dobutamine, and accumulates in cases of renal dysfunction. Milrinone is also a vasodilator, which can limit its use in patients with hypotension. The concomitant use of β-blockers may antagonize the action of dobutamine.

B.J. has responded poorly to IV furosemide, his renal function has deteriorated, and his systolic BP is low. Patients with advanced HF and systemic hypoperfusion often will not tolerate vasodilator therapy. Inotropic agents may be necessary to maintain circulatory function in these patients. According to guidelines, IV inotropic drugs may be considered for patients who have symptomatic hypotension despite adequate filling pressure, who are unresponsive to diuretics and intolerant to vasodilators, or who have worsening renal function. Phosphodiesterase inhibitors are sometimes preferred over dobutamine for patients who are receiving concomitant β-blockers. For the abovementioned reasons, B.J. is a candidate for milrinone therapy. Patients should be on telemetry because milrinone has the potential to cause arrhythmias. Vital signs, SCr, symptom relief, and urine output should be monitored. Once the patient's hemodynamic profile improves, milrinone should be discontinued, and oral furosemide therapy can be resumed. At discharge, the outpatient HF medications should be optimized.

Outpatient Inotropic Infusions

CASE 14-5, QUESTION 2: Are there any indications for using repeated intermittent infusions of inotropic agents as part of a home-care regimen?

The long-term safety and efficacy of inotropic therapy is regarded with skepticism. There are few studies assessing intermittent (e.g., weekly) infusions of dobutamine or milrinone. Nearly all the data on this therapeutic approach are from open-label and uncontrolled trials that compare two inotropic agents without a placebo.[277–281] It is thought that long-term therapy may be cardiotoxic. The only placebo-controlled trial of intermittent infusion of dobutamine was terminated because of excess mortality with dobutamine.[278] Death occurred in 32% of patients treated with dobutamine versus 14% with placebo. Whether this was caused by progression of underlying heart disease, continued drug therapy, or was a cardiotoxic effect remains unknown. No corresponding data exist for milrinone, although a placebo-controlled trial with milrinone failed to support the routine use of IV milrinone as an adjunct to standard therapy in the treatment of patients hospitalized for an acute exacerbation of chronic HF.[274,275] For this reason, the ACA/AHA guidelines indicate that intermittent infusions of dobutamine and milrinone in the long-term treatment of HF, even in advanced stages, should be avoided.[4] Chronic continuous infusions of dobutamine and milrinone are sometimes administered in patients with refractory HF as palliative therapy or in those awaiting transplant. The lowest dose possible should be administered. The HFSA identifies the limited treatment options in advanced HF and proposes patient-centered outcomes (survival vs. quality of life, palliative and hospice care) to be incorporated into care plans.[282]

Ventricular Arrhythmias Complicating Heart Failure

AMIODARONE

CASE 14-5, QUESTION 3: B.J. was stabilized during the next several days and discharged home with furosemide 40 mg daily, enalapril 5 mg twice daily, metoprolol succinate 100 mg daily, aspirin 81 mg daily, and NTG 0.4 mg sublingual to be used as needed for chest pain. His EF is 23%. Laboratory values were normal. ECG monitoring during B.J.'s hospital stay showed normal sinus rhythm, with 15 to 20 asymptomatic PVCs/hour. At that time, it was decided not to treat his arrhythmia other than with metoprolol because he was asymptomatic. For the next several months, he continued to have frequent PVCs during follow-up examinations.

It has now been 5 months and he is still having up to 12 to 15 PVCs/hour. His exercise capacity is limited by SOB after walking about a block despite having enalapril increased to 20 mg/day, metoprolol succinate to 200 mg/day, and adding digoxin 0.25 mg/day. The furosemide is at 40 mg/day because he has edema. A repeat echocardiogram shows an EF of 20%. Is an antiarrhythmic agent indicated for B.J. at this time? What is the agent of choice, and what dose should be given?

PVCs and other arrhythmias are a common complication of LV dysfunction and may be present regardless of whether the patient has had an MI. Approximately 50% to 70% of patients with HF have episodes of nonsustained ventricular tachycardia on ambulatory monitoring.[4] This myocardial irritability may be a result of autonomic hyperactivity or ventricular remodeling. It is not clear whether these rhythm disturbances contribute to sudden death or simply reflect the underlying disease process. Recent studies suggest that bradyarrhythmia or electromechanical dissociation may be associated with sudden death in HF patients with nonischemic cardiomyopathy.[283,284] More importantly, suppression of ventricular ectopy in patients with HF has not been shown to lead to a reduction of sudden death in clinical trials. Neither prophylactic antiarrhythmic therapy nor treatment of asymptomatic PVC after an MI has been proven to improve outcome or survival. Because of concerns about the proarrhythmic effects of most class IA and class IC drugs, treatment with these agents is contraindicated.

Amiodarone has value in patients with HF with arrhythmias because it has antiarrhythmic and coronary vasodilating effects as well as α- and β-blocking properties. It may offer a dual benefit to reduce myocardial irritability and improve the hemodynamics of HF.

In the Grupo de Estudio de la Sobrevida en la Insuficiecia Cardiaca en Argentina (GESICA) study,[285] 516 patients with class II to IV HF symptoms (average EF 20%), and frequent PVCs were randomly assigned to receive either standard treatment (diuretics, vasodilators, digoxin) or a fixed dose of amiodarone plus standard treatment. The dose of amiodarone was 600 mg daily for 2 weeks, then 300 mg/day for at least 1 year. Fewer patients on amiodarone (33.5%) died compared with those receiving standard treatment (41.4%), a statistically significant difference. Similarly, the number of HF-related hospitalizations was reduced with amiodarone.

Somewhat different outcomes were noted in the Veterans Administration (VA) Cooperative Survival Trial of Antiarrhythmic Therapy in Congestive Heart Failure (CHF-STAT) study.[286,287] Entry criteria to this trial were similar to those in the GESICA study, with a primary indicator being more than 10 asymptomatic PVCs per hour on 24-hour monitoring, but without sustained ventricular tachycardia. A higher dose of amiodarone was used, 800 mg for 2 weeks, then 400 mg/day for 1 year. The dose was reduced to 300 mg/day after the first year, with the average

---

follow-up being 45 months. No difference was found between groups for either all-cause mortality or SCD. EF improved more in the patients treated with amiodarone, rising from a baseline average of 24.9% to 33.7%. The corresponding change in the standard treatment group was from a baseline of 25.8% to 29.2% at follow-up. Despite the increase in EF, symptom scores did not differ between the two groups.

Amiodarone does not have a negative effect on mortality as seen with some of the other antiarrhythmic agents. Other factors to consider are the potential for significant side effects with amiodarone (see Chapter 15, Cardiac Arrhythmias) and the drug interaction with digoxin leading to the potential for digoxin toxicity.

The ACC/AHA guidelines do not recommend routine ambulatory ECG monitoring to detect asymptomatic ventricular arrhythmias, and recommend against treatment if such arrhythmias are inadvertently detected.[1,5,6] If symptomatic ventricular arrhythmias should arise or there is determined to be a high risk for sudden death, one of the following should be considered: a β-blocking drug, amiodarone, or an ICD. Nearly all patients with HF should have a β-blocker as part of their regimen because these drugs reduce all-cause mortality, not just sudden death. B.J. continued to have ectopy despite continued use of a β-blocker. Nonetheless, it is decided not to use amiodarone because he is asymptomatic.

IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

CASE 14-5, QUESTION 4: Is B.J. a candidate for an ICD implantation?

Although amiodarone is the preferred antiarrhythmic agent in patients with HF with reduced EF to prevent recurrent AF and symptomatic ventricular arrhythmias, it has not improved survival. Ventricular arrhythmias are associated with a high frequency of SCD in patients with HF. Numerous trials have established the role of ICDs in primary and secondary prevention of SCD. The earliest of the primary prevention trials was the Multicenter Automatic Defibrillator Implantation Trial (MADIT).[288] This study was terminated early because of the survival benefit seen in the ICD group compared with conventional therapy. There was no evidence that amiodarone, β-blockers, or any other antiarrhythmic therapy had a significant influence on the results. Unlike MADIT, the MADIT II[290] study enrolled patients with no documented arrhythmias but with previous MI and LVEF less than 30%. Patients received either an ICD or conventional medical therapy. The primary end point was death from any cause. There was a 31% relative reduction in the risk of death and an absolute reduction of 6% in the ICD group. This was the first trial to show mortality benefits of ICDs in patients with no documented history of abnormal heart rhythms.

The Sudden Cardiac Death in Heart Failure trial (SCD-HeFT) evaluated the efficacy of amiodarone in patients with LV dysfunction (EF $\leq$ 35%).[290] The patients (NYHA class II–III) were receiving conventional therapy and randomly assigned to placebo, amiodarone, or an ICD. Amiodarone was no better than placebo, whereas ICD decreased mortality by 23% ($p = 0.007$). A subgroup analysis showed that patients with class II HF had a greater drop in mortality with ICD use than class III patients, whereas amiodarone decreased survival in class III. The role of amiodarone in patients with NYHA class III needs to be further evaluated before it is routinely used in patients with LV dysfunction.

The ACC/AHA guidelines[1] recommend the use of ICDs in patients after MI with reduced LVEF and who have a history of ventricular arrhythmias. ICDs are also recommended for primary prevention in patients with nonischemic cardiomyopathy and ischemic heart disease who have an LVEF of 30% or less, those with NYHA functional class II or III symptoms while on optimal standard oral therapy, and patients who have reasonable expected survival with a good functional status of one or more years. Patients with ischemic heart disease should receive an ICD at least 40 days after MI. B.J. is currently on optimal HF drug regimen, and his EF is 20%. According to guidelines, B.J. would benefit from ICD implantation.

CARDIAC RESYNCHRONIZATION THERAPY

CASE 14-6

QUESTION 1: C.M., a 49-year-old woman with a history of cardiomyopathy (EF 25%), presents to the HF clinic with NYHA class III symptoms. She reports increased SOB, chest pain, and fatigue. She has been optimized on drug therapy for 3 months. Her medications include metoprolol succinate 200 mg daily, furosemide 40 mg BID, lisinopril 20 mg daily, and spironolactone 25 mg daily, An ECG showed sinus rhythm at a rate of 72 bpm and a QRS duration of 144 ms. Is she a candidate for CRT?

Approximately one-third of the patients with advanced systolic HF exhibit intraventricular or interventricular conduction delays that cause the ventricles to beat asynchronously.[291] Ventricular dyssynchrony is seen on ECG as a wide QRS complex with a left bundle branch block, and can lead to deleterious effects on cardiac function. Patients may present with reduced EF, decreased CO, and presence of NYHA class III or IV HF symptoms. These are all associated with increased mortality.

CRT is the use of cardiac pacing to coordinate the contraction of the left and right ventricles.[77] Initial randomized trials of CRT show reduced HF symptoms and improved exercise tolerance and quality of life. The Comparison of Medical Therapy, Pacing, and Defibrillator in Heart Failure (COMPANION) trial[77] enrolled 1,520 patients with NYHA class II or IV (QRS interval of at least 120 ms, and LVEF ≤35%) who were treated with optimal drug therapy (ACEIs, diuretics, β-blockers, and spironolactone). Patients were randomly assigned to receive optimal drug therapy alone, optimal drug therapy and CRT with a pacemaker, or optimal drug therapy and CRT with ICD (CRT-D). The primary end point was a composite of all-cause mortality and hospitalization. Both CRT and CRT-D groups were associated with a decreased risk of primary end point compared with optimal drug therapy alone. All-cause mortality at 1 year was decreased by 24% in the CRT group (which did not reach statistical significance) and 43% in the CRT-D group.

The results of the Cardiac Resynchronization in Heart Failure study (CARE-HF)[76] extended the findings of the COMPANION trial. CARE-HF demonstrated a significant all-cause mortality reduction for CRT pacing without defibrillator backup (CRT) in patients with HF who received similar medical treatment. The inclusion criteria were NYHA class III or IV, EF of 35% or less, and QRS duration of 120 ms or longer. The primary end point of all-cause deaths and hospitalizations for a CV reason occurred in fewer patients with CRT compared with the optimal drug therapy (39% vs. 55%; $p < 0.001$). Death or hospitalization for worsening HF was also significantly reduced with CRT.

The combined results of CARE-HF and COMPANION confirm the importance of CRT and CRT-D in improving ventricular function, HF symptoms, and exercise tolerance, while also reducing frequency of HF hospitalizations and death.[292] The role of CRT in patients with mild HF symptoms, narrow QRS, chronic AF, and right bundle branch block needs to be explored.

According to the ACC/AHA guidelines,[1] patients with NYHA class III and ambulatory patients with class IV HF should receive CRT (unless contraindicated) if they meet the following criteria: LVEF of 35% or less, presence of a wide QRS (>120 ms), and receiving optimal HF standard medical therapy. Despite optimal

doses of HF medications, C.M. continues to have HF symptoms. CRT therapy could provide incremental benefits beyond what is provided with drug therapy.

CASE 14-6, QUESTION 2: If C.M. presented with NYHA class I or II symptoms, would she be a candidate for CRT therapy? What is the evidence to support CRT in NYHA class I and II patients?

As mentioned in Case 14-6, Question 1, the CARE-HF and COMPANION trials provide strong evidence that CRT induces reverse modeling in patients with symptomatic NYHA class III and ambulatory class IV HF. The next logical step was to evaluate the benefits of CRT therapy in HF patients with milder symptoms. The Multicenter InSynch ICD Randomized Clinical Evaluation (MIRACLE-ICDII)[293] trial randomized class II through IV HF patients but with separate specified end points for class II patients. In this trial, 186 patients with NYHA class II HF, an LVEF of less than 35%, and a QRS of more than 130 ms received a CRT-ICD device. Subjects were randomly assigned to active CRT group (ICD activated and CRT on) or control group (ICD activated and CRT off). The primary end point was progression of HF, defined as all-cause mortality, hospitalizations for HF, and ventricular tachycardia or ventricular fibrillation requiring device intervention. A 15% reduction in HF progression was observed with active CRT, but did not reach statistical significance. At 6 months, patients with active CRT had improved exercise tolerance, but this was not significantly different from the control group. However, there was a significant decrease in ventricular end-systolic volume and increased LVEF after 6 months of therapy. Even though the study results did not translate into improved exercise tolerance, it helped to set the stage for future trials in patients with less symptomatic HF.

The REVERSE trial[74] enrolled 610 participants with NYHA class I or II HF, LVEF less than 40%, and with a QRS duration of more than 120 ms who received a CRT device (with or without ICD) in combination with optimal drug therapy. The patients in the active CRT group had significant improvement in LV end-systolic volume index, LV end-diastolic volume index, and LVEF compared to control. The primary clinical end point (the percentage of patients with worsened clinical composite score) did not reach statistical significance at 12 months in patients enrolled in the United States, but in the European cohort[294] a significant difference was seen at 24 months, primarily driven by the time to first hospitalization The aggregate data from these two clinical trials provided overwhelming evidence that linked CRT with substantial reverse remodeling in mild HF patients.

The MADIT-CRT[75] was the largest randomized trial designed to determine whether CRT-D therapy would reduce the primary end point (all-cause mortality or HF events) when compared with patients receiving ICD-only therapy. The study population involved cardiac patients in NYHA functional class I or II with LVEF of 30% or less and QRS duration of more than 130 ms. There was a 34% ($p < 0.001$) reduction in the primary end point, and a 44% ($p < 0.001$) reduction in HF events when compared with ICD therapy. Patients with CRT-D therapy showed an 11% improvement in LVEF after 1 year, compared with 3% improvement for ICD-alone patients. Both MADIT-CRT and REVERSE excluded patients with AF. Both studies failed to show a benefit for CRT in patients with QRS duration less than 150 ms.

The Resynchronization/Defibrillation for Ambulatory Heart Failure Trial (RAFT)[295] confirmed that CRT benefited patients with a QRS duration of 150 ms or more and in those with left bundle branch block. The RAFT investigators randomly assigned 1,798 patients with NYHA class II or III HF, LVEF of 30% or less, and a QRS duration of at least 120 ms (or a paced QRS of at least 200 ms) to either ICD therapy alone or an ICD with CRT (CRT-D). The primary outcome was a combination of total mortality and HF hospitalization, which was significantly higher in the ICD group compared with the ICD-CRT group (40% vs. 33%, respectively). These findings demonstrate that earlier intervention with CRT-D, in addition to guideline recommended medical and ICD therapy, benefits this patient population.

HEART FAILURE WITH PRESERVED EJECTION FRACTION

CASE 14-7

QUESTION 1: D.F., a 72-year-old white woman, has a 5-year history of HF symptoms, including decreased exercise capacity, SOB, and distended neck veins. She has minimal peripheral edema. History is suggestive of rheumatic fever as a child, but she does not recall having any cardiac symptoms when she was younger, other than being told she had a murmur. Her symptoms are controlled with diuretics. She has HTN but no other medical problems, and all laboratory test findings are normal. Her BP is 155/85 mm Hg, and HR is 90 bpm. Cardiac examination reveals a prominent S_4 heart sound. Echocardiography reveals an EF of 50%. Prior treatment included furosemide, most recently at 40 mg BID. The physician is considering adding a β-blocker or CCB to control the BP and HR. Why might this consideration be appropriate?

This case exemplifies a patient with HF with preserved LVEF (HFpEF), previously referred to as diastolic HF. Risk factors for HFpEF include advanced age, female sex, HTN, and CAD. This diagnosis can be made on the basis of LVH, clinical evidence of HF, a normal EF, and echocardiography findings. The ideal treatment for HFpEF has not been extensively validated. A review of trials evaluating specific drug therapy in HFpEF is listed in Table 14-13. No drug selectively enhances myocardial relaxation without having associated effects on LV contractility or on the peripheral vasculature.[12,52–54,296]

Factors affecting HF control, such as adherence to medication and diet, including NSAID and herbal remedy use, should be appropriately managed along with drug therapy. Symptomatic HFpEF is initially treated similar to other forms of HF, by slow diuresis. Diuresis decreases preload and lessens passive congestion of the ventricles. Excessive lowering of ventricular filling pressures, however, can decrease CO and cause hypotension.

The most common cause of HFpEF is HTN that leads to LVH and decreased cardiac compliance.[297] The ACC/AHA/HFSA guidelines recommend a SPB goal of <130 mmHg in patients with HFpEF and persistent hypertension after management of fluid overload. Drugs that cause regression of LVH (e.g., ACEIs, ARBs, β-blockers) may also slow or reverse structural abnormalities associated with HFpEF.

In the Perindopril in Elderly patients with Chronic HF (PEP-CHF) trial,[298] the ACEI perindopril failed to reduce the incidence of the primary end point (all-cause mortality or HF hospitalizations), but did reduce symptoms and improved functional capacity. The CHARM-preserved trial[156] also failed to show any difference in CV mortality, but fewer hospitalizations were seen in the candesartan group (see Case 14-1, Question 13).

The Valsartan in Diastolic Dysfunction (VALIDD) [299] trial compared the effects of valsartan or placebo added to standard antihypertensive therapy (which included diuretics, β-blockers, CCBs, or α-blockers) in patients with mild HTN and diastolic dysfunction. The hypothesis of this trial was that RAAS inhibition with an ARB would be associated with greater improvement in diastolic function, due to more regression of LVH or myocardial

---

fibrosis. Patients with a history of stage 1 or 2 essential HTN were randomly assigned to receive either valsartan 160 mg, titrated up to 320 mg, or matching placebo. Patients who did not achieve a target BP goal of less than 135/80 mm Hg received additional therapy starting with a diuretic followed by a CCB or a β-blocker, then an α-blocker. ARBs, ACEIs, and aldosterone blockers were excluded. The primary end point was the change in diastolic myocardial relaxation velocity from baseline to 9 months with a secondary end point of change in LV mass. During the study, the placebo group received more concomitant antihypertensive therapy compared with the valsartan group. A small, but significant, increase was seen in diastolic relaxation velocity in both groups from baseline to follow-up, but there was no significant difference between the treatment groups. BP reduction did not differ significantly between the two treatment groups, and was associated with significant improvement in diastolic function. The authors concluded that aggressive BP control —even in mild HTN—was associated with improvement in diastolic dysfunction, irrespective of whether BP reduction was achieved with a RAAS inhibitor or other antihypertensive agent.

CHARM-Preserved[156] investigated the role of candesartan in patients with HFpEF. The trial enrolled 3,023 subjects who met the overall CHARM trial inclusion criteria with an EF of more than 40% (mean, 54%). Subjects had symptomatic HF with normal (preserved) EF. They received either an ARB alone (n = 1,514) or placebo; only 20% of subjects in both groups were taking an ACEI at randomization, 56% a β-blocker, and 11% spironolactone.[156] After a median follow-up of 36.6 months, a trend was noted toward reduction in the primary outcome of CV death or hospital admission for HF in the candesartan group (22%) compared with placebo (24.3%; p

= 0.118). CV deaths and all-cause mortality were nearly identical in both groups, but the total number of hospitalizations for HF was significantly reduced in the candesartan group. The most common side effects with candesartan were hypotension (2.4%), increase in creatinine (4.8%), and hyperkalemia (1.5%). Discontinuation because of an adverse event occurred in 17.8% of those treated with candesartan compared with 13.5% of placebo recipients (p = 0.001) (Table 14-13). Overall, in symptomatic patients with HFpEF, no significant improvement in mortality occurs with candesartan compared with placebo, but there was a significant reduction in HF-related hospitalizations.

I-PRESERVE evaluated irbesartan titrated to 300 mg daily or placebo for the management of HFpEF.[300] The patient population was 60 years of age or older with NYHA class II through IV symptoms, EF of at least 45%, and hospitalized for HF within 6 months prior, or have persistent class III or IV symptoms (n = 4,128). There was no difference in the primary end point (death from any cause or hospitalization for a CV cause) between irbesartan (36%) and placebo (37%). The irbesartan group had more patients experiencing hyperkalemia than placebo. One possible reason for the neutral results of I-PRESERVE included the high rate of dual RAAS blockade at baseline (39% ACEI use in the irbesartan group and 40% in the placebo group; 28% spironolactone use in the irbesartan group and 29% in the placebo group). Based on this high use, the study is less likely to find benefit with ARBs in addition to other RAAS agents. Another potential limitation of the study included the high study discontinuation rate (34%). Overall, irbesartan showed no benefit in reducing morbidity or mortality in HFpEF patients.

Table 14-13

Clinical Trials of Pharmacotherapy in Heart Failure with HFpEF

Study	Patient Population	Therapy Intervention	Outcome	Treatment Duration	Results
Aronow et al.[325]	NYHA III; Prior MI, EF >50%; (n = 21)	Enalapril vs. placebo	NYHA class, treadmill exercise time (seconds)	3 months	Enalapril: NYHA class from 3 ± 0 to 2.4 ± 0.5 (p = 0.005), exercise time from 224 ± 27 to 270 ± 44 (p <0.001) vs. no difference in placebo
Lang et al.[326]	HF symptoms >3 months; EF >50%; (n = 12)	Lisinopril vs. placebo crossover	Dyspnea and fatigue	5 weeks for each treatment arm	No significant differences
Cleland et al.[298] PEP-CHF	Diastolic dysfunction; CV admission within 6 months; EF	Perindopril vs. placebo	Primary: composite of all-cause mortality or hospitalization	Mean 26.2 months	Primary: 23.6% in perindopril group vs. 25.1% in placebo (HR

	>40%; n = 850)		for HF		0.92 [0.70–1.21], p = 0.545)
Zi et al.[327]	NYHA class II or III; EF ≥40%; (n = 74)	Quinapril vs. placebo	6-minute walk test, QoL, NYHA class	6 months	No significant differences
Yusuf et al.[156] CHARM-Preserved	NYHA II–IV; hospitalization for CV causes; EF >40%; (n = 3,023)	Candesartan vs. placebo	Primary: CV death or hospital admission for HF	Median 36.6 months	Primary: 22% in the candesartan group vs. 24% in the placebo group (adjusted HR 0.86 [0.74–1.00], p = 0.051).
Massie et al.[300] I-PRESERVE	NYHA II–IV; hospitalized for HF in last 6 months; EF ≥45%; (n = 4,122)	Irbesartan vs. placebo	Primary: all-cause death or hospitalization for CV causes	Mean 49.5 months	Primary: 36% in the irbesartan group vs. 37% in the placebo group (HR 0.95 [95% CI 0.86–1.05], p = 0.35)
Yip et al.[328]	NYHA II–IV; history of HF in last 2 months; EF >45%; (n = 151)	Ramipril vs. irbesartan	QoL, 6-minute walk test, HF hospital admission	12 months	No significant differences
Warner et al.[329]	Diastolic dysfunction; DOE; EF >50%; SBP >150, <200 mm Hg (n = 20)	Losartan vs. placebo crossover	Exercise time, QoL	2 weeks for each treatment arm	Increase in exercise time (11.3 minutes at baseline, improved to 12.3 ± 2.6 minutes with losartan vs. 11.0 minutes with placebo, p <0.05) and improvement in QoL (25 at baseline, improved to 18 with losartan vs. 22 with placebo); p < 0.05 for both end points
Parthasarathy et al.[330]	Diastolic dysfunction; DOE; EF >40%;	Valsartan vs. placebo	Primary: exercise time	14 weeks	No significant differences

	(n = 152)				
Takeda et al.[331]	NYHA II–III and stage C heart failure; EF ≥45%	Carvedilol vs. placebo	Plasma BNP, NYHA class, exercise capacity	12 months	NYHA class improved by 0.77 (carvedilol) vs. 0.25 (placebo) ($p < 0.02$), exercise capacity in METs improved 0.69 (carvedilol) vs. worsened by 0.07 (placebo) ($p = 0.01$).
Flather et al.[301] SENIORS	HF hospital admission in last year; EF ≤35%; subgroup EF ≥35%	Nebivolol vs. placebo	Primary: composite of all-cause mortality or hospitalization for a cardiovascular cause	Mean 21 months	EF >35%, primary event rate 17.6% in nebivolol and 21.9% in placebo (HR 0.86 [95% CI 0.74–0.99], $p = 0.039$).
Aronow et al.[332]	NYHA II–III; prior Q-wave MI; EF >40%; n = 158)	Propranolol vs. placebo	All-cause mortality, all-cause mortality plus nonfatal MI	32 months	All-cause mortality (56% propranolol group vs. 76% placebo group, $p = 0.007$) and all-cause mortality plus nonfatal MI (59% propranolol vs. 82% placebo, $p = 0.002$).
Setaro et al.[333]	Abnormal diastolic filling; EF >45%; (n = 20)	Verapamil vs. placebo	Exercise capacity	2 weeks for each crossover	Exercise capacity (10.7 minutes at baseline, improved to 13.9 minutes with verapamil vs. 12.3 minutes with placebo, $p < 0.05$).
Ahmed et al.[334] DIG	NYHA I–IV; EF >45%; (n = 988)	Digoxin vs. placebo	Primary: composite of HF hospitalization or mortality	Mean 37 months	102 (21%) in the digoxin group vs. 119 (24%) in the placebo group (HR 0.82 [0.63–1.07], $p = 0.136$).
Pitt et al.[302]	Symptomatic HF;	Spironolactone	Primary:	Mean 39	320 (18.6%) in

TOPCAT	EF >45%; (n = 3445)	vs. placebo	composite of CV death, HF hospitalization, or aborted cardiac arrest	months	the spironolactone group vs. 351 (20.4%) in the placebo group (HR 0.89 [0.77–1.04], p = 0.14).

BNP, B-type natriuretic peptide; CV, cardiovascular; DOE, dyspnea on exertion; EF, ejection fraction; HF, heart failure; HR, hazard ratio; METs, metabolic equivalents; MI, myocardial infarction; NA, not available; NYHA, New York Heart Association; QoL; quality of life; SBP, systolic blood pressure.

β-Blockers or nondihydropyridine CCBs are other classes of drugs of interest in HFpEF. Part of their value is to control HTN, a risk factor for all forms of HF. More specific to HFpEF, β-blockers and CCBs (especially verapamil) possess negative inotropic properties that may favorably influence the pathophysiology of diastolic dysfunction by (a) slowing the HR to allow more time for complete ventricular filling particularly during exercise; (b) reducing myocardial oxygen demand; and (c) controlling BP. Both pharmacologic classes are beneficial in decreasing ischemia in patients with CAD.

Most HF trials with β-blockers demonstrating decreased morbidity and mortality have focused on HFrEF. The Study of the Effects of Nebivolol Intervention on Outcomes and Rehospitalization in Seniors with Heart Failure (SENIORS) study[301] evaluated β-blocker use in elderly HF patients irrespective of LV function. The trial randomly assigned patients to nebivolol or placebo. Nebivolol is a selective β_1-adernergic receptor blocker with vasodilator properties that are mediated through NO release. This effect may be beneficial in elderly patients who tend to have low reserves of endothelial vasodilation.

The primary end point of the study was the combination of all-cause mortality and CV hospital admissions. The end point was significantly reduced by 14% in the nebivolol group, regardless of the EF. Prospective subgroup analyses of the primary outcome by LVEF (≤35% or >35%), sex, or age (≤75 years or >75 years) showed benefits across all subgroups. Patients with EF greater than 35%, however, appeared to benefit a little more than those with low EF%, and all-cause mortality was lower in patients older than 75 years treated with nebivolol compared with placebo. The study reinforces the current recommendations that all HF patients with reduced EF should receive β-blockers. Only 35% of the patients had preserved LV function, and were mostly men. This is not typical of patients with HFpEF, who are frequently women. Further studies are required to define the role of β-blockers in HFpEF.

No randomized controlled trials have demonstrated mortality benefits with CCBs in HFpEF. Nondihydropyridine CCBs can be used in patients who have a contraindication to β-blockers to control BP and HR. Nondihydropyridine CCBs should not be used in patients with HFrEF.

The role of aldosterone antagonists in the management of patients with HFpEF has been evaluated in the Treatment of Preserved Cardiac Function Heart Failure with an Aldosterone Antagonist (TOPCAT) trial.[302] This trial evaluated the impact of spironolactone versus placebo on CV morbidity and mortality in patients older than 50 years of age with an EF greater than 45%. There was no difference in the primary end point (composite of CV death, aborted cardiac arrest, and hospitalization for HF) between the spironolactone and placebo treatment arms with a HR 0.89 (95% CI 0.77–1.04; p = 0.14). There was a significant reduction with spironolactone versus placebo in the secondary end point of hospitalization for HF (HR 0.83 [95% CI 0.69–0.99; p = 0.04]). There has also been a sub-analysis of the TOPCAT study evaluating differences in patients enrolled in the Americas compared to Russia/Georgia relative to the primary and secondary end points. When only looking at patients enrolled from North or South America, there was a significant reduction with the spironolactone-treated patients compared to placebo in the primary end point (HR 0.82 [95% CI 0.69–0.98]) and all secondary end points.[303] Based on these findings, the 2017 ACC/AHA/HFSA Focused Update recommend aldosterone receptor antagonists (class IIb) in HFrEF. An aldosterone receptor antagonist can be considered to decrease hospitalizations in patients with EF ≥ 45%, an elevated BNP or recent hospitalizations. If spironolactone is initiated, then potassium and renal function should be closely monitored (EGFR>30mL/min, creatinine, 2.5mg/dL, potassium <5.0mEq/L).[6]

D.F. fulfills the criteria for having HFpEF, based on her history of long-standing HTN, which has been poorly controlled. Her BP is not at goal, and her HR is elevated. Therefore, antihypertensive therapy is warranted. Tachycardia alone can compromise the ventricle filling time and cause myocardial ischemia. So far, no data support the use of one agent over another. β-Blockers and nondihydropyridine CCBs can each reduce BP and HR. β-Blockers are not considered first-line antihypertensive medications based on recent guidelines without a compelling indication. The use of a nondihydropyridine CCB would be supported in HFpEF patients to reduce both BP and HR. D.F. can be started on a nondihydropyridine CCB such as diltiazem sustained-release (120 mg daily).

Herbal Products and Nutritional Supplements

CASE 14-8

QUESTION 1: W.L., a 60-year-old man recently diagnosed by his naturopath with HF, is concerned about his decreasing exercise capacity and increasing SOB during his morning walks. The naturopath wants to initiate hawthorn and coenzyme Q10 to control his HF symptoms. The patient has uncontrolled HTN (170/85 mm Hg), and has 2+ ankle edema. He distrusts medical doctors because in the past he was given HCTZ for BP reduction, but stopped taking it after a few days because he did not tolerate the urinary urgency it caused. What is the role of herbal products and nutritional supplements in HF?

HAWTHORN

Hawthorn extracts from the leaves and flowers of Crataegus monogyna and Crataegus oxyacantha have been reported to have beneficial effects in mild HF.[304,305] Oligomeric procyanidins and flavonoids are considered the key active ingredients. Hawthorn extracts have shown positive inotropic effects, weak ACE inhibition, vasodilating properties, and increased coronary blood flow in vitro and in animal models. In short-term (8 weeks or less), placebo-controlled trials in patients with the equivalent of NYHA class II HF, modest improvements were noted in exercise tolerance and subjective symptoms as well as decreases in HR and BP. Patients with more advanced HF were excluded. A systematic review by Pittler et al. also concluded that hawthorn extract was efficacious in the treatment of HF when given with standard HF therapy.[306] Conversely, the results of the Hawthorne Extract Randomized Blinded Chronic Heart Failure (HERB-CHF) trial failed to provide any evidence that hawthorn was beneficial in patients with HF who were already receiving standard medical therapy.[307] In clinical trials, side effects of hawthorn include nausea, vomiting, diarrhea, palpitations, chest pain, and vertigo. These side effects are more common when doses exceed 900 mg/day, but in some trials they have not occurred more often than with placebo. The risks and benefits of using hawthorn and digoxin together, both of which have positive inotropic effects, are not known.

To further investigate the longer term benefits of hawthorn, additive effects to conventional therapy and effect on mortality were tested in the Survival and Prognosis: Investigation of Crataegus Extract WS 1442 in Congestive Heart Failure (SPICE) trial.[308] The trial enrolled 2,681 patients with NYHA class II or III, LVEF of 35% or less, who were randomly assigned to hawthorn or placebo for 2 years. Although the study failed to show any clear benefits in the treatment of chronic HF, hawthorn was well tolerated.

COENZYME Q

Coenzyme Q, also known as ubiquinone and ubidecarenone, is an endogenously synthesized provitamin that is structurally similar to vitamin E, serves as a lipid-soluble electron transport carrier in mitochondria, and aids in the synthesis of adenosine triphosphate.[309,310] It may also have membrane-stabilizing properties, enhance the antioxidant effects of vitamin E, and stabilize calcium-dependent slow channels. In animal models, it has positive inotropic effects, although weaker than those of digoxin. More than 18 open-label and double-blind, randomized clinical trials have been conducted

---

of coenzyme Q in patients with HF ranging from NYHA classes II to IV.[309] Doses varied from 50 to 200 mg/day. Patients in many of these trials were also taking diuretics, ACEIs, and digoxin. Different trials used different end point measurements. Positive effects on subjective symptoms, NYHA class improvement, EF, quality of life, and hospitalization rates have all been observed. Two trials, however, failed to demonstrate significant changes in EF, vascular resistance, or exercise tolerance. None of the trials had sufficiently large samples sizes or adequate duration of assessment to detect reduction in mortality. Side effects were minimal, but included nausea, epigastric pain, diarrhea, heartburn, and appetite suppression. Mild increases in lactate dehydrogenase and hepatic enzymes have been rarely reported with coenzyme Q doses in excess of 300 mg/day.

Because no clinical trials have demonstrated improved survival with nutritional/herbal supplements, the current guidelines do not recommend these agents in patients with current or prior symptoms of HFrEF.

W.L. has poorly controlled systolic HTN and HF that is beginning to interfere with his activities of daily life. Although evidence indicates that patients with NYHA class II HF obtain symptomatic improvement with hawthorn and coenzyme Q, this does not address W.L.'s HTN. Conflicting data exist on the value of coenzyme Q in lowering BP.[309] The results of the SPICE trial did not demonstrate any mortality benefits, and no incremental benefits were seen when combined with standard therapy. Uncontrolled HTN in patients with HF leads to cardiac remodeling, and worsening HF. Currently W.L. is presenting with symptomatic HF; therefore, he should be started on a diuretic to alleviate his symptoms. Starting with a 20-mg dose of furosemide and titrating slowly may be one approach. For all of the reasons cited throughout this chapter, one must also argue strongly for starting an ACEI to control his HTN. He should be counseled that the urinary frequency he experienced previously should diminish after a few days. Once he is euvolemic, a β-blocker should be started.

The guidelines clearly state that natural products should not be used to treat symptomatic HF. Agents such as ephedra (which contain catecholamines), ephedrine metabolites, or imported Chinese herbs are contraindicated in HF because of increased risk of mortality and morbidity. No regulatory oversight, quality control, or regulations exist on the use of natural supplements. Because of the widespread use of nutritional supplements and herbal therapies and their potential to cause drug interactions, clinicians should routinely inquire about their use.

Cardiac Arrhythmias

C. Michael White, Jessica C. Song, and James S. Kalus

CORE PRINCIPLES	CHAPTER CASES
ATRIAL FIBRILLATION (AF)/FLUTTER	
① Chest palpitations, light-headedness, and reduced exercise tolerance are the most common symptoms of AF, but stroke is among the severe complications. The goals of therapy are to control the ventricular rate and reduce the risk of stroke.	**Case 15-1 (Questions 1, 2)**
② Digoxin, β-blockers, and nondihydropyridine calcium-channel blockers are appropriate rate-controlling medications. Digoxin is usually adjunctive therapy. Antiarrhythmic drugs are recommended in patients with symptoms but not needed in asymptomatic patients (no symptoms other than palpitations).	**Case 15-1 (Questions 3–7)**
③ Before converting AF to sinus rhythm, assurance of a lack of clot is important but not required if someone is unconscious or hemodynamically unstable. People with a CHA_2DS_2-VASc score of 2 or greater should receive chronic anticoagulant therapy with warfarin, dabigatran, rivaroxaban, edoxaban, or apixaban. Those with a score of 0 do not require antithrombotic therapy, and those with a score of 1 can receive no therapy, aspirin, or anticoagulant therapy based on patient and clinician preference.	**Case 15-1 (Questions 8, 13)**
④ Antiarrhythmic drugs convert patients out of AF 50% of the time, whereas electrical shock is successful 90% of the time. To maintain sinus rhythm after conversion, class Ib agents cannot be used, class Ic agents cannot be used in patients with structural heart disease (left ventricular hypertrophy, myocardial infarction, or heart failure), and class Ia and III agents can increase the risk of torsades de pointes. Propafenone, sotalol, dronedarone, dofetilide, and amiodarone are commonly used antiarrhythmic agents for AF.	**Case 15-1 (Questions 9–12)**
⑤ Atrial flutter is less common than AF, but similar rate control and antiarrhythmic strategies can be tried. Radiofrequency ablation can be used to terminate atrial flutter.	**Case 15-2 (Question 1)**
PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIA (PSVT)	
① PSVT is caused by reentry within the atrioventricular (AV) node. Palpitations and hypotension can occur. The Valsalva maneuver,	**Case 15-3 (Questions 1–6)**

	adenosine, or nondihydropyridine calcium-channel blockers can be used to treat the arrhythmia.	
②	In Wolff–Parkinson–White syndrome patients with PSVT, the use of AV nodal blocking agents such as β-blockers, nondihydropyridine calcium-channel blockers, and digoxin can increase the risk of cardiac arrest. Ablation can destroy the bypass tract and cure the patient.	**Case 15-4 (Questions 1, 2)**

ATRIOVENTRICULAR (AV) BLOCK

①	β-Blockers, digoxin, and nondihydropyridine calcium-channel blockers should be withheld in patients with type 1 second- or third-degree AV block. Atropine can be used to treat this disorder.	**Case 15-5 (Questions 1, 2)**

VENTRICULAR ARRHYTHMIAS

①	In patients with premature ventricular complexes (PVCs) and myocardial infarction, β-blockers are the treatment of choice. Catheter ablation is recommended for those with ventricular compromise due to high PVC burden.	**Case 15-6 (Questions 1, 2)**

②	Patients with myocardial infarction and nonsustained ventricular tachycardia (VT) should receive β-blockers and need to be evaluated to determine whether they should receive an implantable cardioverter-defibrillator (ICD).	**Case 15-6 (Question 1)**
③	Patients with sustained VT should be treated with intravenous antiarrhythmic agents unless they are hemodynamically unstable, in which case they should be electrically converted. To prevent death from arrhythmia recurrence, ICDs are superior to antiarrhythmic drugs, but to decrease the occurrence of painful shocks, both strategies may be used simultaneously.	**Case 15-7 (Questions 1–3)**

TORSADES DE POINTES (TDP)

①	TdP occurs secondary to antiarrhythmic and nonantiarrhythmic medications that prolong the QTc interval. Class Ia and III antiarrhythmic agents, antipsychotic agents, citalopram, fluoroquinolones, macrolides, azole antifungals, and methadone can prolong the QTc interval. Magnesium is the treatment of choice for hemodynamically stable TdP with electrical cardioversion reserved for the hemodynamically unstable.	**Case 15-8 (Questions 1–4)**

CARDIAC ARREST

①	Cardiac arrest should be treated with 2-minute cycles of aggressive cardiopulmonary resuscitation, electrical shock for VT or ventricular fibrillation (VF), epinephrine or vasopressin, and amiodarone for refractory VT or VF according to the Advanced Cardiac Life Support	**Case 15-9 (Questions 1–4),** **Case 15-10 (Question 1),** **Case 15-11 (Questions 1–3)**

guidelines from the American Heart Association.

Adequate circulation depends on continuous, well-coordinated electrical activity within the heart. This chapter reviews and discusses cardiac electrophysiology, arrhythmogenesis, common arrhythmias, and antiarrhythmic treatment.

ELECTROPHYSIOLOGY

Understanding Electrophysiology

CELLULAR ELECTROPHYSIOLOGY

An electrical potential exists across the cell membrane, and the electrical potential changes in a cyclic manner that is related to the flux of K^+, Na^+, and Ca^{2+} ions across the cell membrane.[1] If the change in the membrane potential is plotted against time in a given cycle of a His-Purkinje fiber, a typical action potential results (Fig. 15-1).

The action potential can be described in five phases.[1] Phase 0 is related to ventricular depolarization resulting from sodium entry into the cell through fast sodium channels. On a surface electrocardiogram (ECG), phase 0 is represented by the QRS complex. Phase 1 is the overshoot phase in which calcium enters the cell and contraction occurs. During phase 2, the plateau phase, inward depolarizing currents through slow sodium and calcium channels are counterbalanced by outward repolarizing potassium currents. Phase 3 constitutes repolarization, which on the ECG is represented by the T wave. During phase 4, sodium moves out of the cell and potassium moves into the cell via an active pumping mechanism. During this phase, the action potential remains flat in some cells (e.g., ventricular muscle) and does not change until it receives an impulse from above. In other cells (e.g., sinoatrial [SA] node), the cell slowly depolarizes until it reaches the threshold potential and again spontaneously depolarizes (phase 0). The shape of the action potential depends on the location of the cell (see Fig. 15-1). In both the SA and atrioventricular (AV) nodes, the cells are more dependent on calcium influx than sodium influx, resulting in a less negative resting membrane potential, a slow rise of phase 0, and the capability of spontaneous (automatic) phase 4 depolarization (Fig. 15-1).

The upward slope of phase 0, referred to as V_{max}, is related to the conduction velocity. The steeper the slope, the more rapid the rate of depolarization. Another influence on V_{max} is the point at which depolarization occurs. The less negative the threshold potential, the slower V_{max} will be, and hence conduction velocity is slowed. Drugs can affect V_{max} and conduction velocity by blocking the fast sodium channels or by making the resting membrane potential less negative (e.g., class I agents).

The action potential duration (APD) is the length of time from phase 0 to the end of phase 3. The effective refractory period is the length of time that the cell is refractory and will not propagate another impulse. Both of these measurements can be obtained from intracardiac recordings of the action potential. Class Ia and III agents prolong the refractoriness of the heart.[1]

NORMAL CARDIAC ELECTROPHYSIOLOGY

Automaticity

Automaticity is the ability of cells (often called pacemaker cells) to depolarize spontaneously. These cells are located in the SA and AV nodes and the His-Purkinje system. The SA node is normally the dominant pacemaker because it reaches the threshold faster than other nodes in a normal heart, resulting in 60 to 100 depolarizations per minute.[2] The innate AV node and Purkinje rate of depolarization is 40 to 60 and 40 depolarizations per minute, respectively. In the healthy heart, the AV node and Purkinje fibers are prevented (overridden) from spontaneous depolarization by the more frequent impulses from the SA node.

Conduction

An impulse normally originates in the SA node and travels down specialized intranodal pathways to activate atrial muscle and the AV node. The AV node holds the impulse briefly before releasing it to the bundle of His. It then travels to the right and left bundle branches and out to the ventricular myocardium via the Purkinje fibers. The ECG tracing consists of a series of complexes that correspond to electrical activity in a specific location or anatomic site. By convention, these electrical deflections have been labeled the P wave, QRS complex, and T wave. The P wave represents depolarization of the atria, whereas the QRS complex reflects ventricular depolarization. The T wave reflects repolarization of the ventricles. To evaluate the intact conduction system, conduction intervals at different sites can be obtained. The normal intervals as measured by ECG or intracardiac electrodes are shown in Table 15-1. Drugs and ischemia can alter the conduction and hence the ECG intervals. The effects of antiarrhythmic agents on the ECG are described in Table 15-2.

Table 15-1

Normal Electrocardiographic Intervals

Interval	Normal Indices (ms)	Electrical Activity
PR	120–200	Atrial depolarization
QRS	<140	Ventricular depolarization
QTc[a]	<400	Ventricular repolarization

[a] QTc interval is the QT interval corrected for heart rate. A common method for calculating QTc is the QT interval/(R-R interval)$^{1/2}$ (Bazett formula).

Pathophysiology

ABNORMAL IMPULSE FORMATION

Abnormal impulse formation can arise from abnormal automaticity or triggered activity originating from the SA node (e.g., sinus bradycardia) or other sites (e.g., junctional or idioventricular tachycardia). Causes of abnormal automaticity include hypoxia, ischemia, or excess catecholamine activity.

Triggered activity occurs when there is an attempted depolarization before or after the cell is fully repolarized, but not by a pacemaker cell. These after-depolarizations may occur in phase 2 or 3 (early) or phase 4 (delayed) of the action potential. Early after-depolarizations (EAD) arise from a reduced level of membrane potential and may require a bradycardic state. Torsades de pointes (TdP), a form of polymorphic ventricular tachycardia (VT), is thought to be initiated by EAD. Delayed after-depolarizations, often seen with digoxin toxicity, are thought to be secondary to an overload of intracellular free calcium.

ABNORMAL IMPULSE CONDUCTION

Reentry

The most common abnormal conduction leading to arrhythmogenesis is reentry. A reentrant circuit is formed as normal conduction occurs down a pathway that bifurcates into two pathways (e.g., AV node or left and right bundle branches). The impulse travels along one pathway (Fig. 15-2), but encounters unidirectional antegrade block in the other pathway (see Fig. 15-2). The impulse that passed through the unblocked pathway propagates in a retrograde manner (i.e., moves backward) through the previously blocked pathway. This abnormal impulse can travel down the first pathway again when it is not refractory. Supraventricular and monomorphic VT are both examples of reentrant arrhythmias.

Table 15-2

Pharmacologic Properties of Antiarrhythmic Agents

	Surface ECG				
Type	**PR Interval**	**QRS Interval**	**QT Interval**	**Conduction Velocity**	**Refractory Period**
Ia	0/↑	↑	↑↑	↑↓[a]	↑[b]
Ib	0	0	0	0/↓	↓[b]
Ic	↑	↑↑	↑	↑[b]	0[b]
II	↑↑	0	0	↓[b]	↑[b]
III	0[c]	0	↑↑	0[b]	↑[b]
IV	↑↑	0	0	↓[b]	↑[b]

[a] Conduction increases at low dosages and decreases at higher dosages.

[b] On atrial and atrioventricular nodal tissue.

[c] May cause PR prolongation independent of class III antiarrhythmic activity.

ECG, electrocardiogram.

Block

Another form of abnormal impulse conduction occurs when the normal conducting pathway is blocked and the impulse is forced to travel through nonpathway tissues to cause depolarization. Common examples are left and right bundle branch blocks in the ventricles. A block in one path necessitates retrograde conduction through the opposite bundle to stimulate both ventricles. Nonpathway tissue conducts the electrical impulse more slowly than conduction tissues do.[1]

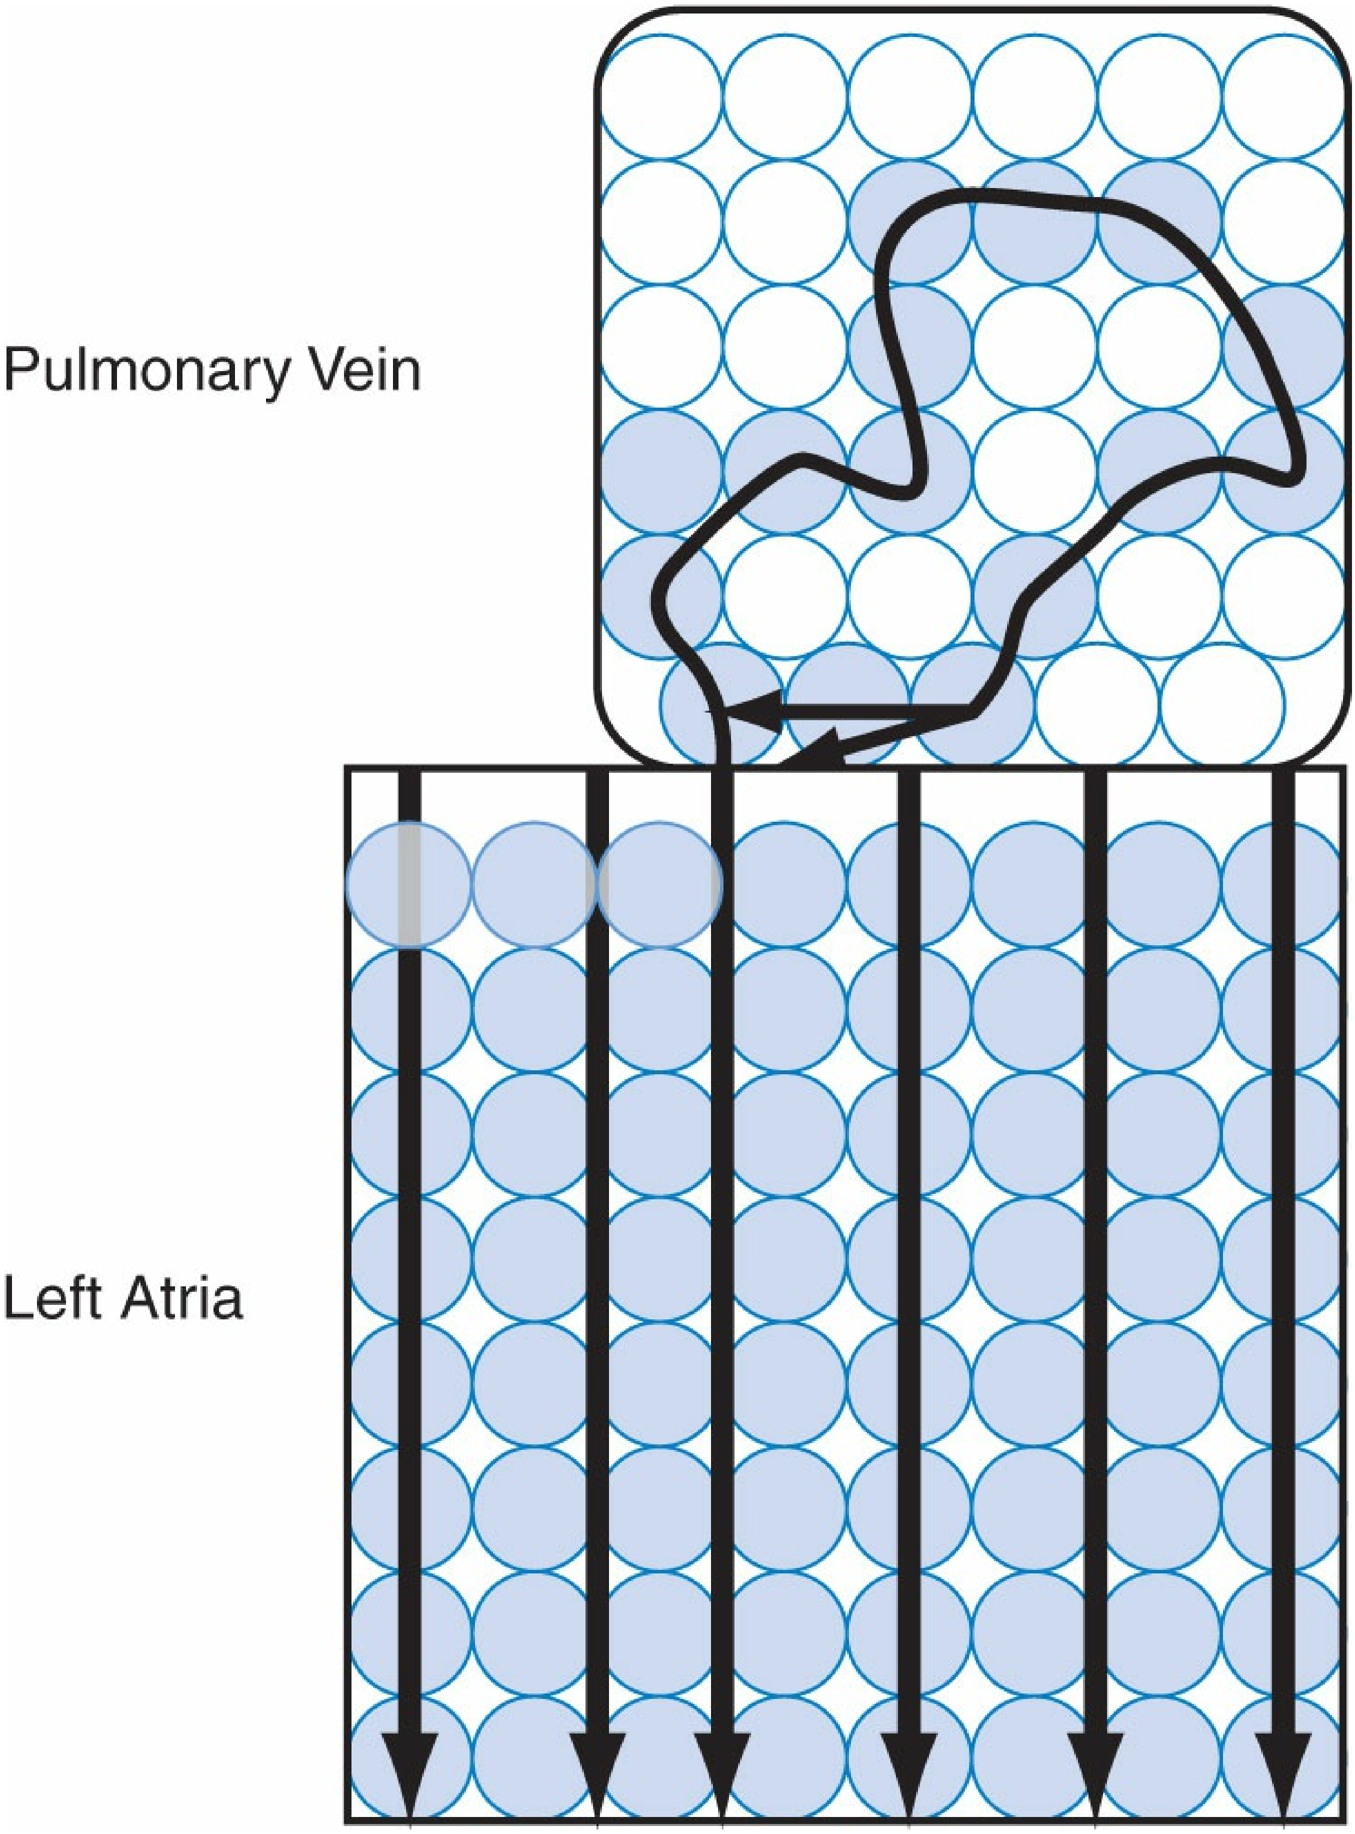

Figure 15-2 Reentrant circuit in the pulmonary vein. In the pulmonary vein there is a mixing of electrically active cells (shaded circles) and electrically inactive cells (white circles). Although the main wave of depolarization goes homogenously down the atria, a small depolarization stimulus enters the pulmonary vein and meanders through the electrically active tissue. In this case, there is a reentrant circuit formed where the impulse can continue to rotate

through the pulmonary vein and a route for it to stimulate the atria as well.

Classification of Arrhythmias

All arrhythmias originating above the bundle of His are referred to as supraventricular arrhythmias. These may include sinus bradycardia, sinus tachycardia, paroxysmal supraventricular tachycardia, atrial flutter, atrial fibrillation (AF), Wolff–Parkinson–White (WPW) syndrome, and premature atrial contractions (PACs). All of these arrhythmias are characterized by normal QRS complexes (i.e., normal ventricular depolarization) unless there is a bundle branch block. Not all of these rhythm changes are necessarily a sign of pathology. For example, athletes with a well-conditioned heart and large stroke volume commonly have slow heart rates (sinus bradycardia). Vigorous exercise is accompanied by transient sinus tachycardia.

Arrhythmias originating below the bundle of His are referred to as ventricular arrhythmias. These include premature ventricular contractions (PVCs), VT, and ventricular fibrillation (VF). Conduction blocks often are categorized separately based on their level or location, which can be a supraventricular site (e.g., first-, second-, or third-degree AV block, see Case 15-6, Question 2) or in the ventricle (e.g., right or left bundle branch block). An alternative method of classifying arrhythmias is based on the rate: bradyarrhythmia (<60 beats/minute) or tachyarrhythmia (>100 beats/minute). There is a website with useful rhythm evaluation tutorials at **http://www.blaufuss.org**.

Antiarrhythmic Drugs

On the basis of their electrophysiologic (EP) and pharmacologic effects, there are four Vaughn-Williams antiarrhythmic drug classes. Class I drugs, sodium-channel blockers, are subdivided further depending on the duration of blockade (class Ia: intermediate; Ib: fast; and Ic: long). Class II drugs are β-adrenergic blockers, class III drugs are potassium-channel blockers, and class IV drugs are calcium-channel blockers. The classification, pharmacokinetics, and adverse effects of these agents are summarized in Table 15-3.

Class Ia and class III antiarrhythmic agents increase repolarization time, the QTc interval, and the risk of TdP. Class II and IV antiarrhythmic agents may decrease heart rate (cause bradycardia), decrease ventricular contractility (decrease stroke volume), and prolong the PR interval (cause second- or third-degree AV block). Class Ib antiarrhythmic agents work only in ventricular tissue, so they cannot be used in AF or atrial flutter. Class Ic antiarrhythmic agents are useful, but should never be used after an MI or with systolic heart failure or severe left ventricular hypertrophy (classified as structural heart diseases) because increased mortality can result. These drugs are discussed in greater detail later.

Table 15-3

Vaughn-Williams Classification of Antiarrhythmic Agents

Drug and Classification	Pharmacokinetics	Indications	Side Effects
Class Ia (can cause torsades de pointes similar to class III agents)			
Quinidine sulfate (83% quinidine; SR) Quinidine gluconate (62% quinidine; SR)	$t_{1/2}$ = 6.2 ± 1.8 hours (affected by age, cirrhosis); V_d = 2.7 L/kg (↓ in HF); liver metabolism, 80%; renal clearance, 20%; C_p = 2–6 mcg/mL, CYP3A4 substrate, CYP2D6 inhibitor, P-glycoprotein inhibitor	AF (conversion or prophylaxis), WPW, PVCs, VT	Diarrhea, hypotension, N/V, cinchonism, fever, thrombocytopenia, proarrhythmia
Procainamide	$t_{1/2}$ = 3 ± 0.6 hours; V_d = 1.9 ± 0.3 L/kg; liver metabolism 40%; renal clearance (GFR + possible CTS) 60%; active metabolite (NAPA)[a] C_p = 4–10 mcg/mL, possible CTS substrate	AF (conversion or prophylaxis), WPW, PVCs, VT	Hypotension, fever, agranulocytosis, SLE (joint/muscle pain, rash, pericarditis), headache, proarrhythmia
Disopyramide (SR and CR forms)	$t_{1/2}$ = 6 ± 1 hours; V_d = 0.59 ± 0.15 L/kg; liver metabolism, 30%; renal clearance, 70%; C_p = 3–6 mcg/mL	AF, WPW, PSVT, PVCs, VT	Anticholinergic (dry mouth, blurred vision, urinary retention), HF, proarrhythmia
Class Ib[b] (cannot be used to treat atrial arrhythmias)			
Lidocaine	$t_{1/2}$ = 1.8 ± 0.4 hours; V_d = 1.1 ± 0.4 L/kg; liver metabolism, 100%; C_p = 1.5–6 mcg/mL	PVCs, VT, VF	Drowsiness, agitation, muscle twitching, seizures, paresthesias, proarrhythmia
Mexiletine	$t_{1/2}$ = 10.4 ± 2.8 hours; V_d = 9.5 ± 3.4 L/kg; liver metabolism, 35%–80%; C_p = 0.5–2 mcg/mL	PVCs, VT, VF	Drowsiness, agitation, muscle twitching, seizures, paresthesias, proarrhythmia, N/V, diarrhea
Class Ic (cannot be used in patients with structural heart disease)			
Flecainide	$t_{1/2}$ = 12–27 hours; CYP2D6 substrate, 75%; renal clearance,	AF, PSVT, severe ventricular arrhythmias	Dizziness, tremor, light-headedness, flushing, blurred

	25%; C_p = 0.4–1 mcg/mL		vision, metallic taste, proarrhythmia
Propafenone	$t_{1/2}$ = 2 hours (extensive metabolizer); 10 hours (poor metabolizer); V_d = 2.5–4 L/kg, CYP2D6 substrate/inhibitor, P-glycoprotein inhibitor	PAF, WPW, severe ventricular arrhythmias	Dizziness, blurred vision, taste disturbances, nausea, worsening of asthma, proarrhythmia
Class III (can cause torsade de pointes similar to class Ia agents, amiodarone, and dronedarone and have lower risk)			
Amiodarone	$t_{1/2}$ = 40–60 days; V_d = 60–100 L/kg; erratic absorption; liver metabolism, 100%; oral F = 50%, C_p = 0.5–2.5 mcg/mL, CYP1A2, 2D6, 2C9, 3A4 inhibitor, P-glycoprotein inhibitor	AF, PAF, PSVT, severe ventricular arrhythmias, VF	Blurred vision, corneal microdeposits, photophobia, skin discoloration, constipation, pulmonary fibrosis, ataxia, hypothyroid or hyperthyroid, hypotension, N/V
Sotalol[c]	$t_{1/2}$ = 10–20 hours; V_d = 1.2–2.4 L/kg; renal clearance, 100%	AF (prophylaxis), PSVT, severe ventricular arrhythmias	Fatigue, dizziness, dyspnea, bradycardia, proarrhythmia
Dofetilide	$t_{1/2}$ = 7.5–10 hours; V_d = 3 L/kg; renal elimination, 60% (GFR + CTS), CYP3A4 substrate	AF or atrial flutter conversion and prophylaxis	Chest pain, dizziness, headache, proarrhythmia
Ibutilide	$t_{1/2}$ = 6 (2–12) hours; V_d = 11 L/kg, C_p = undefined	AF or atrial flutter conversion	Headache, nausea, proarrhythmia
Dronedarone	$t_{1/2}$ = 13–19 hours; V_d = 20 L/kg, T_{max} = 3–6 hours, CYP3A4 substrate, CYP 2D6, 3A4 inhibitor, P-glycoprotein inhibitor, take with food for maximal absorption	AF or atrial flutter prophylaxis	Diarrhea, nausea, dermatitis or rash, bradycardia, hepatotoxicity, pregnancy category X

[a] NAPA is 100% renally eliminated and possesses class III antiarrhythmic activity.

[b] Phenytoin is classified as a class Ib antiarrhythmic.

[c] Possesses both class II and III antiarrhythmic activity.

AF, atrial fibrillation; C_p, steady-state plasma concentration; CR, controlled release; CTS, cation tubular secretion; CYP, cytochrome P-450; F, bioavailability; GFR, glomerular filtration rate; HF, heart failure; NAPA, N-acetylprocainamide; N/V, nausea and vomiting; PAF, paroxysmal atrial fibrillation; PSVT, paroxysmal supraventricular tachycardia; PVC, premature ventricular contraction; SLE, systemic lupus erythematosus; SR, sustained release; $t_{1/2}$, half-life; V_d, volume of distribution; VF, ventricular fibrillation; VT, ventricular tachycardia; WPW, Wolff–Parkinson–White syndrome.

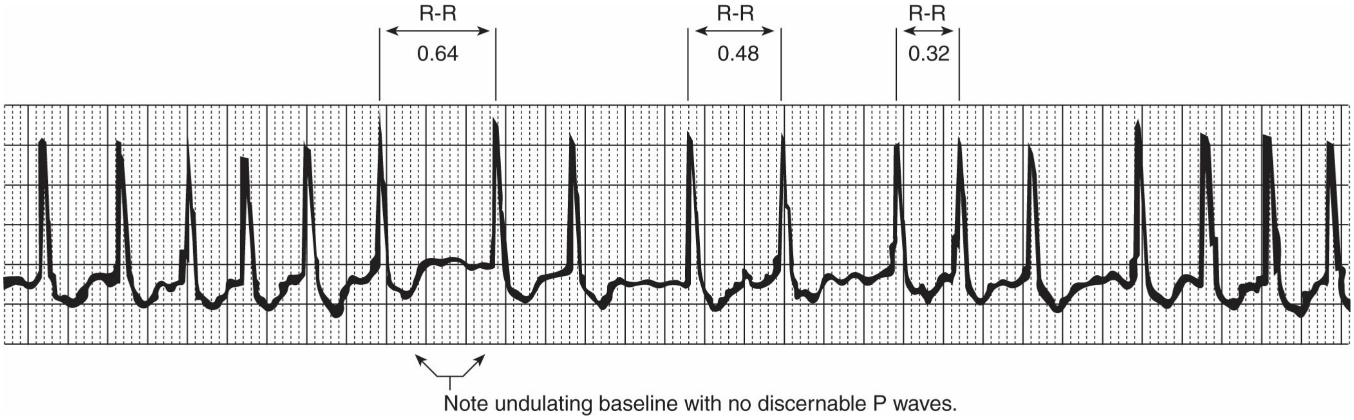

Figure 15-3 Atrial fibrillation. Note the irregularly irregular R-R intervals, undulating baseline without definitive P waves, normal width of the QRS complexes, and ventricular rate of 140 beats/minute.

SUPRAVENTRICULAR ARRHYTHMIAS

The specific arrhythmias include (a) those primarily atrial in origin, such as AF, atrial flutter, paroxysmal sinus tachycardia, ectopic atrial tachycardia, and multifocal atrial tachycardia; and (b) AV nodal reentrant tachycardia (AVNRT) and AV reentrant tachycardia (AVRT) involving accessory pathways within the atria or ventricle. AVNRT and AVRT often self-terminate and are paroxysmal (episodic) in nature; thus, they are commonly referred to as paroxysmal supraventricular tachycardias (PSVT). The most common supraventricular arrhythmias are AF, atrial flutter, and PSVT.

Atrial Fibrillation and Atrial Flutter

AF is usually initiated when a depolarization stimulus arising from an ectopic focus or reentrant circuit impacts the atria while the tissue is in the vulnerable period. The vulnerable period in the atria and ventricles occurs during the first half of the QRS complex; this period is vulnerable because the net charge is near normal but the ion concentrations of sodium, calcium, and potassium inside and outside the cells are radically different. Stimulation during the vulnerable period causes multiple ectopic foci to arise and attempt to pace the atria with no single pacemaker in control, eliminating discernable P waves on the ECG (Fig. 15-3) and eliciting a rapid, ineffective writhing of the atrial muscle with a classic “irregularly irregular” ventricular rate. In contrast, atrial flutter (Fig. 15-4) is characterized by typical sawtooth atrial waves, at a rate of 280 to 320 beats/minute, and a variable ventricular rate, depending on the nature of the AV block present (e.g., 2, 3, or 4 atrial beats for each ventricular beat or 2:1, 3:1, or 4:1 block). In most cases, the ventricular rate is approximately 150 beats/minute. Episodes of atrial flutter can progress to AF if the ectopic atrial depolarization stimulus impacts the surrounding atrial tissue in the vulnerable period. When patients initially experience AF, the episodes are usually short lived, and spontaneous conversion occurs. The pattern of erratic initiation and termination of AF is termed paroxysmal atrial fibrillation (PAF), and if enough AF events occur in close proximity to each other, the duration of subsequent AF events increases in length and the event degenerates into persistent AF. In persistent AF, the AF episode will continue until the heart is electrically or chemically converted out of the rhythm. With time, persistent AF degenerates into permanent AF, in which normal sinus rhythm cannot be achieved and sustained. An example of PAF is presented in the following section.

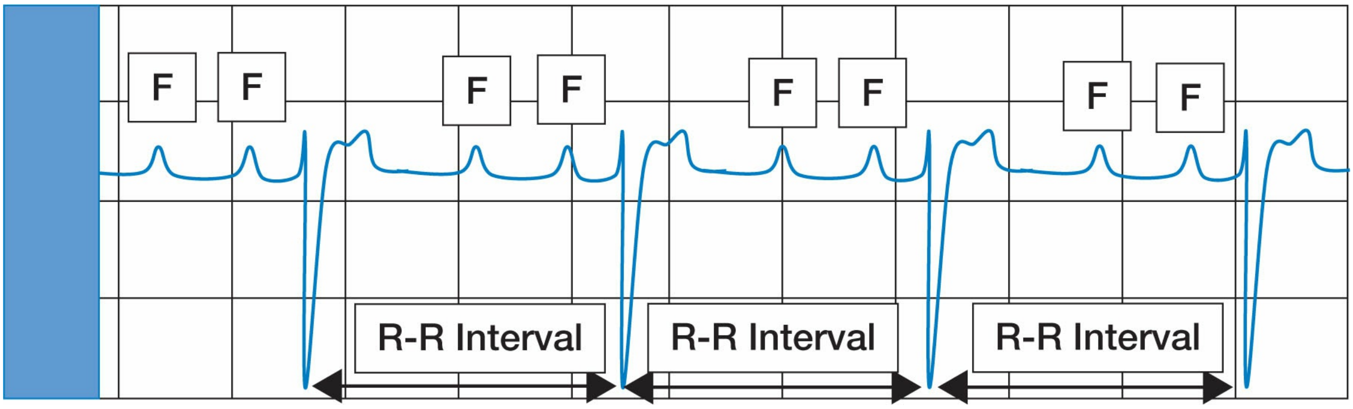

Figure 15-4 Atrial flutter. Note the sawtooth appearance of the rhythm strip. F denotes Flutter waves with consistent R-R spacing.

CLINICAL MANIFESTATION AND UNDERLYING CAUSES

CASE 15-1

QUESTION 1: J.K., a 66-year-old man, presents for a routine checkup in the clinic. His medical history includes type 2 diabetes mellitus and systolic HF for the last 5 years, hypertension, and gout. There is no history of rheumatic heart disease, MI, pulmonary embolism, or thyroid disease. Medications include metformin 1 g twice daily, lisinopril 40 mg every day, furosemide 40 mg twice daily, metoprolol succinate 50 mg twice daily, and allopurinol 300 mg/day. J.K. does not smoke or drink alcohol. Physical examination reveals a blood pressure (BP) of 136/84 mm Hg, pulse of 70 beats/minute in normal sinus rhythm, respiratory rate of 12 breaths/minute, and temperature of 98.2°F. His body mass index is 32 kg/m^2. What factors in J.K.'s past medical history predispose him to development of AF? What is his 10-year risk of developing AF?

AF is commonly associated with, or a manifestation of, other diseases or disorders (Table 15-4).[3,3a] When treatable underlying causes are present, they should be corrected because this may resolve the AF. A risk prediction tool highlights common factors associated with the development of AF, particularly older age, male gender, hypertension, heart failure, obesity, and valvular disease.[4,5] In a small percentage of patients who do not have underlying heart disease, AF is called "lone" AF and usually has a more benign course.

J.K. has several risk factors for the development of AF within the next 10 years, including the presence of treated hypertension, heart failure, his age, and his sex. A detailed scoring system is described in the referenced manuscript but is beyond the scope of this chapter. Using his risk factors, his 10-year risk of developing AF would be greater than 30%.[4]

Consequences of Atrial Fibrillation

CASE 15-1, QUESTION 2: Two years later, J.K. presents with complaints of dyspnea on exertion (DOE) and palpitations for the last 2 weeks. He experienced palpitations of shorter duration three times in the last year, but these were not associated with DOE. On physical examination, he is found to have rales. Cardiac examination reveals an irregularly irregular rhythm without murmurs, gallops, or rubs. His jugular veins are distended 4 cm, but no organomegaly is found. His extremities have 1+ pitting edema. The ECG shows AF (see Fig. 15-3), and the chest radiograph is compatible with mild pulmonary congestion. A cardiac echocardiogram reveals the atrial size to be less than 5 cm (normal) and a left ventricular ejection fraction of 35%. What clinical findings demonstrated by J.K. are typically associated with AF? What are the likely consequences of his AF?

The most common complaint in patients with AF, as with J.K., is palpitations (the sensation of the heart beating rapidly or unusually in the chest). This is a result of the rapid ventricular rate, which typically ranges from 100 to 160 beats/minute. The R–R interval (time from the R wave in one QRS complex to the R wave in the next complex) is irregularly irregular (random irregularity). During AF, the atrial kick or the atria's contribution to stroke volume is lost. Because the atrial kick may account for 20% to 30% of the total stroke volume, this, coupled with rapid ventricular rates and irregular R–R interval spacing during AF, can cause symptoms of inadequate blood flow such as light-headedness, dizziness, or reduced exercise tolerance. However, some patients are asymptomatic except for the palpitations. Depending on the underlying ventricular function, signs of HF, such as DOE and peripheral edema, may develop, as experienced by J.K. Conversely, underlying HF may precipitate AF.

Table 15-4

Causes of Atrial Fibrillation and Flutter

Alcohol	Nonrheumatic Heart Disease
Atrial septal defect	Pericarditis
Cardiac surgery	Pneumonia
Cardiomyopathy	Pulmonary embolism
Cerebrovascular accident	Sick sinus syndrome
Chronic obstructive pulmonary disease	Stimulants Thyrotoxicosis
Fever	Trauma

Hypothermia	Tumors
Ischemic heart disease	Wolff–Parkinson–White syndrome
Mitral valve disease	

Patients with AF are at risk for thrombotic stroke (see Stroke Prevention section below).[6] With the chaotic movement of the atria, normal blood flow is disrupted, and atrial mural thrombi (usually in a pouch called the left atrial appendage) may form. The risk of stroke increases after restoration of normal sinus rhythm, which allows more efficient cardiac contractility and expulsion of the thrombus. Patients with nonvalvular AF have a fivefold increase in the risk of stroke; this risk increases as patients have an increased number of associated risk factors. Other concurrent diseases that may increase the risk of stroke are HF, cardiomyopathy, thyrotoxicosis, congenital heart disease, and valvular heart disease. Because of the high risk of stroke and significant impact of stroke on patient outcomes, pharmacologic stroke prophylaxis is often indicated. Selection of an appropriate antithrombotic regimen for the patient with AF must be based on assessment of the underlying stroke and bleeding risk. Risk stratification in AF is performed with the use of the CHA_2DS_2-VASc scoring system. A CHA_2DS_2-VASc score is calculated by assigning one point each for the presence of congestive heart failure, hypertension, diabetes, vascular disease, age of 65 to 74 years, or female gender and two points for age of 75 years or greater or a history of stroke. Points are totaled, and the subsequent score correlates with stroke risk.[7]

TREATMENT OF ATRIAL FIBRILLATION

Goals of Therapy

CASE 15-1, QUESTION 3: What are the therapeutic goals and general approaches used to treat AF in patients like J.K.?

The two primary goals of treatment are to control the ventricular response rate and to reduce the risk of stroke. In some cases, a third therapeutic goal may be conversion to normal sinus rhythm.

Ventricular Rate Control

Digoxin

CASE 15-1, QUESTION 4: J.K. is given a 1-mg loading dose of digoxin, followed by a 0.25-mg every day maintenance dose. What is the purpose of administering digoxin? What are the relative advantages and disadvantages of digoxin compared with other agents to control ventricular rate?

Table 15-5

Agents Used for Controlling Ventricular Rate in Supraventricular Tachycardias[a]

Drug	Loading Dose	Usual Maintenance Dose	Comments
Digoxin	10–15 mcg/kg LBW up to 1–1.5 mg IV or PO for 24 hours (e.g., 0.5 mg initially, then 0.25 mg every 6 hours)	PO: 0.125–0.5 mg/day; adjust for renal failure (see Chapter 14)	Maximal response may take several hours; use with caution in patients with renal impairment
Esmolol	0.5 mg/kg IV for 1 minute	50–300 mcg/kg/minute continuous infusion with bolus between increases	Hypotension common; effects additive with digoxin and calcium-channel blockers
Propranolol	0.5–1.0 mg IV repeated every 2 minutes (up to 0.1–0.15 mg/kg)	IV infusion: 0.04 mg/kg/minute PO: 10–120 mg TID	Use with caution in patients with HF or asthma; additive effects seen with digoxin and calcium-channel blockers
Metoprolol	5 mg IV at 1 mg/minute	PO: 25–100 mg BID	Use with caution in patients with HF or asthma; additive effects seen with digoxin and calcium-channel blockers
Verapamil	5–10 mg (0.075–0.15 mg/kg) IV for 2 minutes; if response inadequate after 15–30 minutes, repeat 10 mg (up to 0.15 mg/kg)	IV infusion: 5–10 mg/hour PO: 40–120 mg TID or 120–480 mg in sustained-release form daily	Hypotension with IV route; AV blocking effects are additive with digoxin and β-blockers; may increase digoxin levels
Diltiazem	0.25 mg/kg IV for 2 minutes; if response inadequate after 15 minutes, repeat 0.35 mg/kg for 2 minutes	IV infusion: 5–15 mg/hour PO: 60–90 mg TID or QID or 180–360 mg in extended-release form daily	Response to IV therapy occurs in 4–5 minutes; hypotension; effects additive with digoxin and β-blockers

[a] AV nodal ablation is a nonpharmacologic alternative to control the ventricular response, but the effect is permanent and may require chronic ventricular pacing afterward.

AV, atrioventricular; BID, 2 times a day; HF, heart failure; LBW, lean body weight; PO, orally; IV, intravenously; QID, four times a day; TID, three times a day.

The first treatment goal is to slow the ventricular response rate, which allows better ventricular filling with blood. Table 15-5 displays the agents commonly used to control the ventricular response and, provides typical loading and maintenance doses. Because of its direct AV node-blocking effects and vagomimetic properties, digoxin prolongs the effective refractory period of the AV node and reduces the number of impulses conducted through the AV node (negative dromotropy).[6]

There are several limitations associated with digoxin use in AF. Digoxin has a slow onset of action. After an intravenous (IV) dose, it will take more than 2 hours for the onset of effect and 6 to 8 hours for the maximal effect, which is markedly slower than other negative dromotropic agents.[8] Digoxin is also less effective than β-blockers and nondihydropyridine calcium-channel blockers during states of heightened sympathetic tone (e.g., exercise or emotional stress), a common precipitant of PAF. [7–11] The 2014 American Heart Association/American College of Cardiology/Heart Rhythm Society Guidelines for the management of patients with AF recommend that digoxin use be reserved for control of ventricular response rate in patients with impaired left ventricular function or HF or for use as an add-on therapy when treatment with a β-blocker or calcium-channel blocker provides inadequate rate control.[12] Patients who require rate control of AF and have a lower BP may also benefit from rate control with digoxin. It should also be noted that digoxin serum concentrations may be increased when combined with P-glycoprotein inhibitors such as verapamil, propafenone, quinidine, flecainide, and amiodarone.[13–15] Normally, P-glycoprotein in the brush border membrane of intestinal enterocytes pumps digoxin into the lumen of the gut reducing its bioavailability and pumps digoxin out of the body via the renal tubules (see Chapter 14, Heart Failure, for discussion of digoxin and digoxin drug interactions).

CASE 15-1, QUESTION 5: J.K. has diabetes, which increases the risk for diabetic nephropathy. Would the dosing be changed if J.K. had renal dysfunction?

J.K.’s renal function is normal. If he had significant renal dysfunction, both the loading and the maintenance doses of digoxin would need to be altered. A loading dose is used to achieve a therapeutic level and volume of distribution of digoxin is reduced in patients with renal dysfunction. The digoxin maintenance dose is highly dependent on renal clearance, because digoxin is eliminated 50% to 75% unchanged in the urine (see Chapter 14, Heart Failure, for further discussion of digoxin dosing in patients with normal and impaired renal function). Although the usual digoxin target range is generally 0.5 to 1.0 ng/mL in the management of patients with heart failure,[16] higher serum concentrations may be necessary when using digoxin as a rate control agent for J.K.

β-Adrenergic Blocking Agents

CASE 15-1, QUESTION 6: What other drugs can be used for ventricular rate control, and what are their relative advantages and disadvantages compared with digoxin?

β-Adrenergic blocking agents are another class of negative dromotropic agents used in AF. Propranolol, metoprolol, and esmolol are available for IV administration. Each agent rapidly controls the ventricular rate both at rest and during exercise. β-Blockers are the first choice in high catecholamine states such as thyrotoxicosis and postcardiac surgery. However, given their negative inotropic effects, β-blockers should be used cautiously to acutely control the ventricular response in patients with decompensated HF. Even though β-blockers are used to treat systolic HF (e.g., bisoprolol, carvedilol, and metoprolol), they need to be started at low doses and titrated slowly for several weeks to therapeutic doses[2] (see Chapter 14, Heart Failure). When trying to achieve rapid rate control, more aggressive dosing may be needed. β-Blockers should also be avoided in patients with asthma because of their β_2-blocking properties, and blood glucose levels should be monitored more closely in patients with diabetes mellitus because the signs and symptoms of hypoglycemia (except sweating) can be masked.

Calcium-Channel Blockers

Nondihydropyridine calcium-channel blockers are also effective in slowing ventricular rate at rest and during exercise. Both verapamil and diltiazem can be administered IV for a rapid (4–5 minutes) reduction in heart rate.[12] Nondihydropyridine calcium-channel blockers should not be used in patients presenting with decompensated HF.[7] They work through their effect on slow calcium channels within the AV node. Although the duration of action produced by bolus dosing is short, both agents can be administered either as a continuous drip or orally. Given the ability of calcium-channel blockers to cause arteriolar dilation, a transient decrease in BP may be seen. IV calcium pretreatment can be used to attenuate the BP decrease among patients with hypotension, near-hypotensive BP, or left ventricular dysfunction. Calcium pretreatment does not appear to diminish the negative dromotropic effects of nondihydropyridine calcium-channel blockers.[17–20] Verapamil is contraindicated in patients with an ejection fraction less than 35% and diltiazem should be used with caution in HF with a reduced EF. Verapamil increases the concentrations of other cardiovascular drugs such as digoxin, dofetilide, simvastatin, and lovastatin.[21] Verapamil and diltiazem are good alternatives to β-blockers in asthmatics.[7]

For chronic therapy, oral negative dromotropic agents (usually a β-blocker or nondihydropyridine calcium-channel blocker) are recommended. If higher dose monotherapy with one of these drugs is needed to control symptoms but is associated with intolerable side effects, adding lower dose digoxin to a β-blocker or calcium-channel blocker is recommended.[7,11,22–24]

J.K. has signs of mild HF, so digoxin is a reasonable choice, although short-term IV diltiazem is often used in this type of patient as well. IV verapamil and β-blockers may worsen the signs and symptoms of HF, and the β-blockers may mask signs of hypoglycemia in J.K. The goal of rate control should be a resting heart rate between 60 and 80 beats/minute and an exercising heart rate between 90 and 115 beats/minute.[7] A recent study has explored the use of a more lenient target resting heart rate (<110 beats/minute) and reported similar patient outcomes as compared with a more strict target heart rate (resting heart rate <80 beats/minute).[25] This study may suggest that it could be acceptable for a patient's heart rate to be greater than 80 beats/minute, if there is difficulty in achieving this level of heart rate control and in asymptomatic patients or those with HF and a preserved EF.[7,26]

Rate Control versus Rhythm Control

CASE 15-1, QUESTION 7: After loading of digoxin, J.K.'s heart rate is still 120 beats/minute and he continues to experience palpitations. His BP is 100/60 mm Hg, and his symptoms of heart failure are improving, but he still complains of mild shortness of breath. The decision is made to cardiovert J.K. to normal sinus rhythm. Is J.K. a good candidate for a rhythm control strategy and if so, why? What is the likelihood that J.K. will be successfully converted to normal sinus rhythm?

The use of a rhythm control strategy has become much less common during the last several years. This change is because of the completion of several studies comparing the effect of a rate or rhythm control strategy on patient outcomes.[27–32] The AFFIRM study (Atrial Fibrillation Follow-up Investigation of Rhythm Management), a randomized, multicenter study, was one of the largest to compare rate control with rhythm control for management of AF. AFFIRM enrolled 4,060 patients with AF and a risk of stroke.[27] The primary end point was all-cause mortality. Antiarrhythmic drugs were chosen at the discretion of the treating physician, but greater than 60% of the patients received amiodarone or sotalol as the initial antiarrhythmic agent. Rate control agents included digoxin, β-blockers, and nondihydropyridine calcium-channel blockers. After a mean follow-up of 3.5 years, there was a trend toward lower overall mortality ($p = 0.08$) with significant reductions in hospitalizations (10% lower; $p = 0.001$) and TdP (300% lower; $p = 0.007$) in the rate control group. Therefore, using rhythm control in patients with AF rather than rate control does not improve outcomes and increases the risk of hospitalizations and TdP.

The default long-term treatment strategy for most patients should be a rate control strategy, in which heart rate is controlled and anticoagulation is provided, if indicated. However, rhythm control is necessary when patients experience symptoms despite adequate rate control, when heart rate cannot be adequately controlled with currently available treatments, or if patients cannot tolerate the adverse effects of rate-controlling medications. J.K.'s heart rate is not adequately controlled with digoxin and an oral β-blocker. A nondihydropyridine calcium-channel blocker could be added or the β-blocker dose could be increased in order to better control his heart rate; however, his BP may not tolerate the increased dose of the β-blocker or the addition of a nondihydropyridine calcium-channel blocker. Therefore, pursuit of a rhythm control strategy is warranted.

Likelihood of successful conversion to, and maintenance of, normal sinus rhythm is determined by the duration of the arrhythmia, underlying disease processes, and left atrial size.[33] Duration of AF for more than 1 year significantly reduces the chances of maintaining a normal sinus rhythm.[34] When the atrial size exceeds 5 cm, there is less than a 10% chance of maintaining normal sinus rhythm at 6 months. J.K.'s chance of being maintained in normal sinus rhythm is good because the duration of his AF is short and the echocardiogram revealed only slight enlargement of his left atrium.

Conversion to Normal Sinus Rhythm

CASE 15-1, QUESTION 8: Warfarin treatment is begun and J.K.'s prothrombin time is to be maintained at an international normalized ratio (INR) of 2 to 3. J.K. is scheduled for a transesophageal echocardiogram (TEE) to determine whether cardioversion can be performed during this admission. How does a TEE help to determine whether cardioversion can be performed, and why is warfarin therapy being used?

When the onset of AF is less than 48 hours, the likelihood of atrial clot formation is low. However, if patients are at a high risk for stroke, they should receive an anticoagulant (unfractionated heparin, low-molecular-weight heparin, factor Xa, or direct thrombin inhibitor) as soon as possible surrounding the cardioversion, followed by long-term anticoagulation.[7] When the duration of AF is greater than 48 hours, or if duration is unknown, then an oral anticoagulant agent (warfarin, dabigatran, factor Xa inhibitor) should be given for 3 weeks before cardioversion at doses providing an INR between 2 and 3 if using warfarin.[7] Studies in patients with AF showed that those who were anticoagulated with warfarin before cardioversion had a lower incidence (0.8%) of emboli than those who were not anticoagulated (5.3%).[35] Alternatively, a TEE can be used to determine whether atrial clots have formed.[7,36] Atrial clots form most often in small side pouches on the atria called atrial appendages.[37] Because the frequency of right atrial appendage thrombosis is half that of left atrial appendage thrombosis in AF patients, the risk of stroke is enhanced much more than the risk of pulmonary embolism.[37]

If no clot is observed on TEE, then there is low risk for stroke with cardioversion of AF.[36] However, if an atrial clot is evident on TEE, J.K. would need to be adequately anticoagulated for

---

3 weeks before cardioversion to prevent embolization of the clot and stroke. If cardioversion is successful, patients should remain on an oral anticoagulant agent for at least 4 weeks after cardioversion because normal atrial contraction may not return for up to 3 weeks, and patients may be at risk of late embolization.[38] The decision to provide long-term oral anticoagulation is dependent on the patient's underlying stroke and bleeding risk. This will be discussed further below.

Chemical Conversion—Ibutilide, Propafenone, Flecainide

CASE 15-1, QUESTION 9: J.K. was found to be free of atrial clots. Chemical cardioversion with ibutilide is planned for tomorrow. If J.K. fails to convert with ibutilide, he will be electrically cardioverted later in the day. How does ibutilide therapy compare with the other therapeutic choices for chemical cardioversion?

The most effective method of cardioversion is by direct current (DC) cardioversion (see Electrical Cardioversion section below). However, the use of DC cardioversion may be undesirable if the patient is a poor candidate for conscious sedation or if the patient is not willing to undergo DC cardioversion. In these situations, pharmacologic cardioversion may be attempted. Many class I and III antiarrhythmic agents have been evaluated for efficacy in placebo-controlled trials for conversion of AF or atrial flutter to normal sinus rhythm. The available agents with the most positive data for chemical conversion include IV ibutilide, oral propafenone, oral flecainide, oral and IV amiodarone, and oral dofetilide. This section will focus on ibutilide, propafenone, and flecainide.

IV ibutilide, a class III antiarrhythmic agent with potassium-channel blocking and slow sodium-channel enhancing effects, was the first agent that the US Food and Drug Administration (FDA) approved for the termination of recent-onset AF and atrial flutter.[39] Ibutilide is administered as a 1-mg infusion for 10 minutes, followed by another 1-mg infusion for 10 minutes if conversion has not occurred by 10 minutes after the infusion. The conversion rate for recent-onset AF is 35% to 50%; the conversion rate is 65% to 80% in atrial flutter. In a retrospective study of hospital inpatients with either AF or atrial flutter, 50% of patients converted initially (41% conversion AF, 65% atrial flutter), but only 33% of patients left the hospital in sinus rhythm. If the duration of AF or atrial flutter before cardioversion was fewer than 15 days, significantly more patients remained in sinus rhythm at discharge compared with patients who had AF or atrial flutter for more than 15 days before cardioversion.[40] As is the case with most class III antiarrhythmic agents, the main adverse effect is TdP, which occurred in approximately 4% of patients. Ibutilide should be avoided in patients with hypokalemia, hypomagnesemia, QT prolongation, and a low ejection fraction (<30%). Aside from the risk of TdP, therapy is well tolerated.[41–43]

Propafenone is a class Ic agent with β-blocking properties. When given in doses of 450 to 750 mg orally (600 mg was the most common dose), the initial conversion rate in patients with AF ranged from 41% to 57%. In contrast to ibutilide, no patients experienced ventricular arrhythmias (including TdP), but a risk of hypotension, bradycardia, and QRS prolongation was noted.[44–46]

Oral flecainide is another class Ic antiarrhythmic agent. In one study, 300 mg oral flecainide converted 68% of patients to sinus rhythm within 3 hours and 91% of patients by 8 hours. The efficacy in atrial flutter has yet to be established. Sinus node dysfunction, prolongation of intraventricular conduction, dizziness, weakness, and gastrointestinal (GI) disturbances have been reported.[47,48]

A β-blocker or nondihydropyridine calcium-channel antagonist should be administered ≥30 minutes before administering the Vaughan Williams class Ic agent to prevent a rapid ventricular response due to 1:1 AV conduction during atrial flutter.[7] J.K. is not a candidate for these agents due to his structural heart disease.

Electrical Conversion

CASE 15-1, QUESTION 10: J.K. received two doses of IV ibutilide. After the second dose, he converted to normal sinus rhythm for only 5 minutes, then returned to AF. J.K. is scheduled for electrical cardioversion in 6 hours. What is electrical cardioversion? How efficacious and safe is it?

DC cardioversion quickly and effectively restores 85% to 90% of patients with AF to normal sinus rhythm.[38] If DC conversion alone is ineffective, it can be repeated in combination with antiarrhythmic drugs.[7,49] In one study, the success rate of electrical cardioversion was significantly higher in AF patients (duration of AF averaged 119 days) with ibutilide pretreatment (1 mg) compared with those without pretreatment (100% vs. 72%; $p = 0.001$).[49] This is because ibutilide pretreatment lowered the energy requirement for atrial defibrillation by 27% ($p = 0.001$). TdP occurred in 3% of patients receiving ibutilide, all of whom had an ejection fraction less than 20%. Flecainide, propafenone, amiodarone, and dofetilide could also be considered for enhancing DC cardioversion.[7]

DC cardioversion is clearly indicated for patients who are hemodynamically unstable. A reason one may wish to avoid DC conversion is because anesthesia (short-acting benzodiazepine, barbiturate, or propofol) is required for the procedure.

Maintenance of Sinus Rhythm

CASE 15-1, QUESTION 11: J.K. is discharged after successful DC conversion. However, when he returns for a follow-up visit 2 weeks later, he is found to be in AF again. He again reports frequent palpitations. His physician would like to initiate an antiarrhythmic drug to maintain normal sinus rhythm. Which agent(s) would be the best option for this patient?

To choose the best antiarrhythmic agent for J.K., the efficacy and adverse effect profiles for each agent should be reviewed. Class Ia, Ic, and III antiarrhythmic drugs (see Tables 15-2 and 15-3) prevent the recurrence of AF. Flecainide, sotalol, dofetilide, and dronedarone are approved by the FDA for maintenance of sinus rhythm. Propafenone and amiodarone are commonly used as well.

Flecainide and Propafenone

The class Ic agents flecainide and propafenone are effective in suppressing AF.[50–54] The efficacy rate may be as high as 61% to 92% for flecainide.[55,56] Flecainide and possibly other class Ic agents are proarrhythmic, especially in patients with structural heart disease, and they should be avoided in such patients. Propafenone, a class Ic agent with β-blocking properties, is as efficacious as flecainide and is relatively safe in patients without ischemic heart disease and an ejection fraction greater than 35%; it may be preferred in patients who require additional AV blockade to control ventricular response. In a direct comparison with flecainide (200–300 mg/day), propafenone (450–900 mg/day) was equally safe and effective. Over the course of 12 months, a similar percentage of patients (approximately 12% in each group) did not have adequate control of their arrhythmia. Adverse events were comparable and occurred in 10.3% of patients on flecainide and 7.7% of patients on propafenone. Of all the adverse events noted, only one patient who was receiving propafenone developed a ventricular arrhythmia. Another 1-year comparative study of propafenone versus flecainide demonstrated similar efficacy, but this study showed a trend toward better tolerability in the flecainide group.[57,58]

Class III Agents

CASE 15-1, QUESTION 12: J.K. is to begin dofetilide today. He is admitted to the hospital for dofetilide initiation. Why would J.K. need to be admitted for dofetilide initiation? Is it necessary to initiate all antiarrhythmic medications in the hospital?

Class III agents (sotalol, dofetilide, amiodarone, dronedarone) prolong refractoriness in the atria, ventricles, AV node, and accessory pathway tissue and can prevent recurrence of AF. All of these agents act by blocking potassium channels; however, sotalol also has additional β-blocking properties.[59–61] Both amiodarone and dronedarone block sodium channels and calcium channels, and have antiadrenergic effects in addition to potassium-channel blocking properties.[59,61]

Sotalol, Amiodarone, Dofetilide, and Dronedarone

The efficacy of sotalol in delaying the recurrence of AF was evaluated in a double-blind, placebo-controlled, multicenter, randomized trial that enrolled 253 patients with AF or atrial flutter.[62] The median times to recurrence were 27, 106, 229, and 175 days with placebo, sotalol 160 mg/day (divided in two doses), sotalol 240 mg/day (divided in two doses), and sotalol 320 mg/day (divided in two doses), respectively. Sotalol is contraindicated in patients with a creatinine clearance (CrCl) of less than 40 mL/minute because of the fact that the drug is largely renally cleared and can cause TdP in high concentrations. In a comparative study versus propafenone, sotalol was similarly effective in producing at least a 75% reduction in AF recurrence (79% of patients on propafenone vs. 76% on sotalol). Bradycardia, dizziness, and GI disturbances were the most common intolerable side effects.[63] Sotalol should not be used in patients with systolic heart failure owing to the negative inotropic effects of the drug. It may be useful as a first-line agent in patients with AF and concomitant underlying coronary artery disease or in patients with no cardiovascular disease.[7]

Amiodarone is more effective at maintaining sinus rhythm than sotalol and propafenone.[64] The Canadian Trial of Atrial Fibrillation (CTAF) compared the ability of low-dose amiodarone (200 mg/day) versus propafenone (450–600 mg/day) and sotalol (160–320 mg/day) to prevent recurrence of AF.[64] After a mean follow-up of 16 months, 35% of the amiodarone-treated patients had a recurrence of AF versus 63% in the combined group with sotalol and propafenone ($p = 0.001$). In view of its unusual pharmacokinetics and potential serious adverse effects (see Table 15-3 and Case 15-7, Question 2), amiodarone is only recommended as a first-line choice for patients with HF, for which it has specific safety data, or for patients with significant left ventricular hypertrophy.[7] Amiodarone could also be used when other agents such as sotalol, propafenone, or dofetilide have failed.[7,65]

Dofetilide has been shown to be an effective pharmacologic agent for conversion to, and maintenance of, normal sinus rhythm. Two clinical trials, EMERALD (European and Australian Multicenter Evaluative Research on Atrial Fibrillation Dofetilide)[66] and SAFIRE-D (Symptomatic Atrial Fibrillation Investigation and Randomized Evaluation of Dofetilide),[67] have shown conversion rates of 30% in patients with AF or atrial flutter receiving higher doses of dofetilide. Patients failing chemical conversion received electrical conversion. If this conversion succeeded, they were continued on dofetilide for 1 year. At 1 year, 60% of those converted were still in sinus rhythm with the 500-mcg dose. Also, dofetilide appears to exert neutral effects on mortality rates in HF and post-MI patients.[68,69]

Dofetilide dose is based on the patient's CrCl; the doses are 500, 250, and 125 mcg twice daily with CrCl greater than 60, 40 to 60, and 20 to 39 mL/minute, respectively. Drug interactions pose a significant problem with dofetilide. Cimetidine, ketoconazole, prochlorperazine, megestrol, and trimethoprim (including in combination with sulfamethoxazole) inhibit active tubular secretion of dofetilide and can elevate dofetilide plasma concentrations.[60] Because the incidence of TdP is directly related to dofetilide plasma concentrations, concomitant use with these agents is contraindicated.[70] Concomitant administration of dofetilide with verapamil or hydrochlorothiazide increases the incidence of TdP by an unclear mechanism and is contraindicated as well.[60] Concurrent use of agents that can prolong the QTc interval is not recommended with dofetilide.[70] Dofetilide also undergoes metabolism by the cytochrome P-450 CYP3A4 isoenzyme to a minor extent. Therefore, inhibitors of this isoenzyme (e.g., azole antifungal agents, protease inhibitors, serotonin reuptake inhibitors, amiodarone, diltiazem, nefazodone, zafirlukast) should be coadministered with caution with dofetilide. Other agents that can potentially increase dofetilide levels (through inhibition of tubular secretion) include metformin, triamterene, and amiloride. Hence, these agents should be cautiously coadministered with dofetilide.[70]

Dofetilide is considered a first-line agent for patients with heart failure or coronary artery disease, as the impact on mortality in this patient population is neutral.[7] Dofetilide can also be considered as a first-line agent for patients without cardiovascular disease, but should be avoided in patients with severe left ventricular hypertrophy.[7]

Dronedarone is structurally and pharmacologically similar to amiodarone; however, it lacks iodine, and it has a much smaller volume of distribution than amiodarone. The lack of iodine may make dronedarone less likely to cause thyroid-related or other adverse effects.[61] Dronedarone has been shown to have modest efficacy in maintaining sinus rhythm when compared with placebo. The rate of recurrence of AF at 1 year is approximately 40%, and the number of days to recurrence is nearly doubled with dronedarone.[71] The major clinical trial evaluating dronedarone was the ATHENA study. The primary end point of ATHENA was a composite of death or cardiovascular hospitalization, and patients received either dronedarone 400 mg twice daily or placebo for at least 1 year.[72] The primary composite end point was significantly reduced from 39.4% with placebo to 31.9% with dronedarone. This reduction in the composite was completely attributable to the reduction in cardiovascular hospitalizations, most of which were related to AF recurrence. GI events were the most common type of adverse effect with dronedarone in this study. It should be noted that patients with recent decompensated HF or New York Heart Association (NYHA) class IV heart failure were excluded from this trial. The exclusion of patients with severe or unstable heart failure was related to negative findings that led to the early discontinuation of the ANDROMEDA study.[73] ANDROMEDA was designed as a safety study, to evaluate the impact of dronedarone on mortality in patients with HF. Patients admitted with NYHA class III or IV systolic HF were included in this study. The study was stopped early because of an approximate doubling in the risk of death with dronedarone as compared with placebo. Therefore, dronedarone is contraindicated in a patient with severe or recently decompensated HF. Based on the findings of the PALLAS study, dronedarone should be avoided in patients with permanent AF as well.[74] This study found that the rate of stroke, heart failure, and cardiovascular death was increased when dronedarone was used in this patient population. Dronedarone has also been compared directly with amiodarone.[75] In this study, dronedarone was less effective than amiodarone, but was less likely than amiodarone to cause thyroid, neurologic, skin, or ocular adverse effects. GI adverse effects were more common with dronedarone.[75] Dronedarone is appropriate as a first-line agent for patients with AF and concomitant coronary artery disease, and possibly left ventricular

hypertrophy or in patients with no cardiovascular disease. Dronedarone should not be used in a patient with severe HF symptoms or a recent hospitalization for HF, but may be used with mild, well-controlled HF.[7,73]

In view of J.K.'s HF, sotalol, propafenone, and flecainide would not be indicated. Although dronedarone may be better tolerated than amiodarone, it would be contraindicated because J.K. was recently admitted with decompensated HF. Therefore, the only available options for J.K. would be either dofetilide or amiodarone, both of which have been proven safe in patients with HF. Selection between dofetilide and amiodarone could be based on renal function, the presence of any major drug interactions, or the desire to avoid adverse effects with amiodarone.

Dofetilide was approved with the requirement for in-hospital initiation because of the relatively high risk of TdP in clinical trials. ECG monitoring is required for patients being initiated on dofetilide for a minimum of 3 days in a properly equipped facility. The initial regimen is determined by the patient's estimated CrCl. The QTc interval must be measured (using a 12-lead ECG) 2 to 3 hours after the first dose and each subsequent dose while the patient is hospitalized. If the QTc interval increases by greater than 15% or if it surpasses 500 ms (>550 ms in patients with ventricular conduction abnormalities) after the first dose, the dofetilide regimen should be reduced by 50%. If the QTc interval exceeds the above parameters any time after the second subsequent dose, dofetilide should be discontinued.[76]

Sotalol may also be arrhythmogenic in high doses, and the risk of inducing TdP has prompted its manufacturer to mandate a minimum of 3 days of ECG monitoring in a properly equipped facility during therapy initiation as well.[76] Further, during initiation and titration, QTc intervals should be monitored 2 to 4 hours after each dose. In fact, most antiarrhythmic agents for AF should probably be initiated in the inpatient setting, with the exception of amiodarone owing to the low risk of proarrhythmia with this drug.[7]

STROKE PREVENTION

Antithrombotic Therapy

CASE 15-1, QUESTION 13: J.K. is discharged from the hospital on dofetilide 500 mcg twice daily, which is appropriate given his CrCl of 92 mL/minute. He has been doing fine for 2 weeks after discharge. Should J.K. remain on warfarin therapy? Could any other antithrombotic options be considered?

Patients with nonvalvular and valvular AF have a 5- and 17-fold increased risk for stroke compared with patients without AF, respectively.[4,5] Stroke can lead to death or significant neurologic disability in up to 71% of patients, with an annual recurrence rate as high as 10%.[77]

In three large, randomized trials, patients with nonvalvular AF benefited from antithrombotic therapy.[78–81] In the Stroke Prevention in Atrial Fibrillation (SPAF) study, both aspirin 325 mg/day and warfarin (titrated to an INR of 2.0–4.5) reduced the risk of stroke significantly with an acceptable level of hemorrhagic complications.[80] The results of SPAF II, a direct comparison of warfarin and aspirin, indicated that warfarin was more effective than aspirin in preventing stroke.[81] These results were verified by the Copenhagen AFASAK study, which found warfarin to be significantly better than aspirin and placebo at preventing cerebral emboli and overall vascular deaths (cerebral and cardiovascular).[78] An oral direct thrombin antagonist (dabigatran) and oral factor Xa antagonists (rivaroxaban, apixaban, edoxaban) are now available. These newer anticoagulant agents have been shown to have similar or better efficacy and safety compared to warfarin.[82–84]

Dabigatran is approved by the FDA to reduce the risk of stroke and systemic embolism in patients with nonvalvular AF.[85] In the Re-Ly trial, dabigatran 110 mg twice daily and 150 mg twice daily was compared with warfarin in patients with a $CHADS_2$ score of 1 or more (average $CHADS_2$ score of 2.1). The $CHADS_2$ score is a tool used to estimate stroke risk. In this study the lower dose of dabigatran was noninferior to warfarin for stroke prevention but was associated with less bleeding. High-dose dabigatran was superior to warfarin for stroke prevention but comparable in bleeding.[86] The most common nonbleeding adverse event in this study was GI upset. It should also be noted that dabigatran capsules should not be chewed or opened.

The three oral factor Xa inhibitors that are currently approved for prevention of stroke and systemic embolus in patients with AF include rivaroxaban, apixaban, and edoxaban. Each of these agents have been compared directly to warfarin using fairly similar study designs.[82–84] Rivaroxaban and edoxaban were found to be noninferior to warfarin in stroke/systemic embolus prevention, while apixaban was found to be superior to warfarin in efficacy. Major bleeding occurred less frequently with edoxaban and apixaban and at a similar rate with rivaroxaban, compared to warfarin. Although efficacy and safety of all of the new agents differed when compared with warfarin, there are no direct comparisons between any of the newer antithrombotic options. As such, no firm conclusions can be drawn regarding the optimal agent to choose. However, in a patient who is perceived to have a high bleeding risk, it is reasonable to select apixaban or edoxaban, given the bleeding risk advantage of these agents relative to warfarin.[83,84]

Some differences between the newer agents could be considered when selecting an anticoagulant regimen for a patient. For example, each agent has different recommendations for use with kidney dysfunction. None of the newer oral agents should be used in patients with a CrCl less than 15 mL/minute. The "renal doses" of rivaroxaban (15 mg/day with CrCl of 15–49 mL/minute) and edoxaban (30 mg/day with CrCl of 15–50 mL/minute) were evaluated in the ROCKET AF and ENGAGE AF TIMI 48 studies, whereas the renal dose adjustment recommended for dabigatran (75-mg twice daily dose for those with a CrCl of 15–30 mL/minute) was based on extrapolated pharmacokinetic data.[82,84,87] Apixaban does not require dosage adjustment based on a CrCl, but adjustment should occur if the patient has two or more high-risk characteristics (body weight <60 kg, serum creatinine >1.5 or age >80 years). Interestingly, edoxaban is less effective and should not be used when CrCl is greater than 95 mL/minute. Therefore, edoxaban, apixaban, or rivaroxaban may be a more evidence-based option than dabigatran for a patient with poor kidney function and edoxaban would be an inappropriate choice for the patient with very good kidney function.[82–85]

The drug interaction profiles of the oral direct thrombin inhibitor or oral factor Xa inhibitors are favorable compared to that of warfarin. All of the newer anticoagulant options interact with rifampin. Rivaroxaban and apixaban also interact with other strong inhibitors and inducers of both the P-glycoprotein and CYP 3A4 systems. Dabigatran interacts with inhibitors of P-glycoprotein (ketoconazole, dronedarone); however, no change in therapy is required unless the interacting drugs are used in a patient who also has a CrCl less than 50 mL/minute. At this time, no notable interactions have been identified with edoxaban, other than the interaction with rifampin. Although the number of interactions with the newer anticoagulants is fewer than with warfarin, it will still be important to evaluate for the presence of interactions at therapy initiation and when the drug therapy regimen is changed. An advantage of dabigatran and the oral factor Xa antagonists is that these agents do not require frequent monitoring and dosage adjustment in order to assure an appropriate level of

---

anticoagulation. A potential disadvantage is that it is often not possible to monitor the extent of anticoagulation in the setting of bleeding or when an urgent procedure or surgery is needed. In addition, strategies for reversal of these agents are not well defined, in contrast to the reversal approach with warfarin. Best available evidence suggests that concentrated blood factor products (4-factor prothrombin complex concentrates and FEIBA) may be options for reversing the effects of these agents; however, specific reversal agents are likely to be commercially available in the near future.[88] Hemodialysis can also be used to remove dabigatran, in the setting of life-threatening bleeding.[88]

Generally, patients with a CHA_2DS_2-VASc score of 2 or greater should receive anticoagulant therapy for stroke prophylaxis.[7] Warfarin (INR target 2–3), dabigatran, rivaroxaban, apixaban are all recommended as antithrombotic agents for stroke prophylaxis.[7] Edoxaban was not approved at the time of publication of the 2014 guidelines for AF and is not currently included, but has FDA approval. No therapy, an antithrombotic agent, or aspirin alone could be used in patients with a CHA_2DS_2-VASc score of 1 and stroke prophylaxis is not required if a patient's CHA_2DS_2-VASc score is 0. If a patient's INR is difficult to control on warfarin, a direct thrombin inhibitor or oral Xa antagonist could be used.[7] It should be noted that patients with AF and valvular disease should only be treated with warfarin for stroke prophylaxis as data with valvular AF are either unfavorable or unavailable with the newer agents in this patient population.[89]

Even though J.K. is in normal sinus rhythm at this time, in the AFFIRM trial, only 73% and 63% of patients randomized to rhythm control remained in sinus rhythm at 3 and 5 years, respectively.[26] As such, the use of an antiarrhythmic drug does not eliminate the risk of stroke, and in fact, patients may return to AF and not be aware they are no longer in normal sinus rhythm. J.K. has a CHA_2DS_2-VASc score of 4 and does not appear to have any factors that would suggest a high bleeding risk (no recent history of GI bleeding, etc.). Therefore, he should continue to receive anticoagulation for stroke prophylaxis.[7] Although J.K. is currently taking warfarin, there would be no reason he could not receive any of the other available anticoagulants.

CASE 15-2

QUESTION 1: M.P. is a 38-year-old woman who has had frequent episodes of atrial flutter for the past 2 years. She has no other medical history and is taking metoprolol 50 mg twice daily. She does not want to take the drug any longer because it reduces her exercise tolerance. Does the treatment of atrial flutter differ from the treatment of AF and what is the role of radiofrequency catheter ablation for M.P.?

Atrial flutter is an unstable rhythm that often reverts to sinus rhythm or progresses to AF. If atrial flutter is episodic, its underlying cause should be identified and treated if possible. If a patient remains in atrial flutter, the treatment goals (control of ventricular rate, return to normal sinus rhythm) are the same as those for AF. Similar agents and doses can be used to control the ventricular response. Chemical conversion, low-energy (<50 J) DC cardioversion, or rapid atrial pacing may acutely convert atrial flutter back to sinus rhythm, but the recurrence of atrial flutter is high.

Radiofrequency catheter ablation therapy could be used as a nonpharmacologic treatment for atrial flutter and AF.[7] With both atrial flutter and AF, an EP study is performed to identify whether ablation can be performed. Various sections of the atria and pulmonary veins (where they intersect with the atria) are probed with a catheter that delivers cardiac pacing. If an area is stimulated with pacing and an atrial ectopic or reentrant focus is recognized, that area could be ablated. Ablation destroys tissue that is integral either to the initiation or to the maintenance of the arrhythmia by delivering electrical energy through electrodes on the catheter. If the focus of the arrhythmia is in the atrial tissue (typically for atrial flutter), then the focus itself is ablated. This procedure is successful in 75% to 90% of cases and can be recommended for patients with atrial flutter who are drug-resistant or drug-intolerant, or do not desire long-term therapy. In AF, an ectopic focus originating in the pulmonary veins can often initiate the arrhythmia. In this case, circumferential ablation, in which a circle of ablated tissue is made around the pulmonary veins, is performed. Circumferential ablation does not prevent the ectopic impulses from the pulmonary veins from occurring; however, it does prevent propagation of the impulse into the atria and may reduce the recurrence of AF. Recent data comparing ablation to antiarrhythmic drug therapy in patients with PAF suggest that ablation is more effective in preventing recurrence of AF than medications.[90]

Radiofrequency ablation therapy may be suitable for M.P. However, if exercise intolerance is her primary complaint, this might be relieved by switching M.P. to another drug, such as verapamil.[91,92]

Paroxysmal Supraventricular Tachycardia

CLINICAL PRESENTATION

CASE 15-3

QUESTION 1: B.J., a 32-year-old woman, presents to the emergency department (ED) complaining of fatigue and palpitations. She has had similar episodes approximately twice a year for the past 2 years, but has not sought medical attention for them. She is in no apparent distress and has a temperature of 98.0°F, heart rate of 185 beats/minute, BP of 95/60 mm Hg, and respiratory rate of 12 breaths/minute. Her ECG (Fig. 15-5) shows regular rhythm with a heart rate of 185 bpm. The P waves cannot be found, and the QRS complex is 110 ms (normal, <120 ms). She has no past medical history of note.

What is the clinical presentation of PSVT, and what are the consequences of this arrhythmia?

PSVT often has a sudden onset and termination. At the time of PSVT, the heart rate is usually 180 to 200 beats/minute. As illustrated by B.J., patients experience palpitations and often nervousness and anxiety. In patients with a rapid ventricular rate, dizziness, and syncope can occur, and the rhythm may degenerate to other serious arrhythmias. Angina, HF, or shock may be precipitated by underlying severe atherosclerosis or left ventricular dysfunction but this is not part of B.J.'s past medical history. There is no evidence that patients with episodes of PSVT are at an increased risk of stroke.

ARRHYTHMOGENESIS AND REENTRY

CASE 15-3, QUESTION 2: What is the arrhythmogenic mechanism of PSVT?

AV nodal reentry is the most common mechanism of paroxysmal supraventricular arrhythmias (see Fig. 15-2). Here AV nodal impulses are blocked in one of two directions in an antegrade fashion but when reaching the end, conducts in a retrograde fashion setting up a circular reentrant circuit. Reciprocating tachycardias occur when there is an accessory pathway for conduction of impulses between the atria and ventricles, like with WPW syndrome, and PSVT results (Fig. 15-6).

White syndrome. **A:** A bifurcation of an impulse, one propagated fast and another slow. **B:** The slow impulse in **(A)** can send impulses in a retrograde fashion. **C:** The reentry from **(A)** to **(B)** can be self-sustaining. **D:** Normal impulse conduction through the AV node, but abnormal retrograde conduction up an accessory pathway, as would be seen in a patient with Wolff–Parkinson–White syndrome.

TREATMENT

CASE 15-3, QUESTION 3: B.J. tries the Valsalva maneuver, and her ventricular rate is reduced to 150 beats/minute; the other parameters are unchanged. She is given IV adenosine 6 mg, administered over 1 minute, with no effect on the PSVT rate. Another dose of adenosine 12 mg given over 1 minute has no effect. No side effects are noted from therapy. What treatment options can be used if B.J. is hemodynamically unstable? What is the Valsalva maneuver? What is the probable reason for B.J.'s unresponsiveness to adenosine? Are there any drug interactions that might diminish adenosine's effect?

Nondrug Treatment

Valsalva Maneuver

Although her BP is low at 95/60 mm Hg, B.J. is maintaining an adequate perfusion pressure, so vagal maneuvers should be attempted first. Two common vagal techniques are pressure over the bifurcation of the internal and external carotid arteries and the Valsalva maneuver (forcible exhalation against a closed glottis, similar to bearing down to have a bowel movement). The increase in pressure induced by these maneuvers is sensed by the baroreceptors, causing a reflex decrease in sympathetic tone and an increase in vagal tone. The increase in vagal tone will terminate in 10% to 30% of cases.[92] If B.J. was hemodynamically unstable or becomes hemodynamically unstable, she should receive synchronized DC cardioversion.

Drug Therapy

Adenosine

Because most PSVT episodes involve reentry in the AV node, drugs that block the AV node (negative dromotropic drugs) are generally effective. Adenosine, a purine nucleoside that exerts a transient negative chronotropic and dromotropic effect on cardiac pacemaker tissue,[93] is considered the drug of choice for the acute treatment of PSVT because of its rapid and brief effect. An initial 6-mg IV bolus is given; if this is unsuccessful within 2 minutes, it can be followed by one or two 12-mg IV boluses, up to a maximum of 30 mg. Because of its short half-life (9 seconds), adenosine should be administered as a rapid bolus (over 1–3 seconds), followed immediately by a saline flush. Adenosine begins to be metabolized immediately after entering the bloodstream; therefore, B.J.'s failure to respond is likely attributed to the prolonged (1-minute) infusion time.

Theoretically, adenosine may be ineffective or higher doses may be required in patients who are receiving theophylline because theophylline is an effective adenosine receptor blocker. Larger doses of other methylxanthines (caffeine, guarana) may also theoretically interact like theophylline. Conversely, concomitant use of dipyridamole may accentuate adenosine's effects because dipyridamole blocks the adenosine uptake (and subsequent clearance).

CASE 15-3, QUESTION 4: B.J. is given 12 mg adenosine IV during 2 seconds, followed by a 20-mL normal saline flush. Thirty seconds later, she complains of chest tightness and pressure. What is the explanation for these symptoms?

B.J. is experiencing a common side effect of adenosine. Patients receiving adenosine should be warned that they may feel transient chest heaviness, flushing, or a feeling of anxiety. Shortness of breath and wheezing may be observed in patients with asthma. The denervated heart of the patient who has undergone heart transplant is particularly sensitive to adenosine; therefore, lower doses of adenosine should be used.

Calcium-Channel Blockers

CASE 15-3, QUESTION 5: B.J. is still in PSVT. What other acute therapeutic options should be considered at this time?

Nondihydropyridine calcium-channel blockers, verapamil, and diltiazem, can be used in patients with PSVT. Verapamil (5–10 mg or 0.075–0.15 mg/kg IV given over 2 minutes) achieves peak therapeutic effects in 3 to 5 minutes after dosing and can be repeated at 10- to 15-minute intervals to a maximal dose of 20 mg if needed. The elderly should receive the verapamil infusion over 3 minutes to minimize the risk of adverse events. Diltiazem is given as a 0.25-mg/kg IV bolus over 2 minutes, and a second bolus of 0.35 mg/kg can be given 15 minutes later if the effect is inadequate. Both of these calcium-channel blockers have an 85% conversion rate.[94] However, verapamil should not be used in patients with wide complex tachycardia of unknown origin because it may lead to hemodynamic compromise and potentially VF. β-Blockers and digoxin can be used if calcium-channel blockers and adenosine fail.

CASE 15-3, QUESTION 6: B.J. is given 5 mg IV verapamil, followed by an additional 5 mg 10 minutes later. She converts to normal sinus rhythm 3 minutes after the second dose. Because she has experienced symptoms that could be attributed to PSVT in the past, she may be a candidate for chronic therapy to slow conduction and increase refractoriness at the AV node. Which agents have been evaluated for this indication? Is there a role for radiofrequency catheter ablation therapy for PSVT?

Radiofrequency catheter ablation is frequently used as a definitive treatment for PSVT. EP testing is used to determine the location of the reentrant tract, which then can be ablated, thereby interrupting accessory pathways and reentrant circuits. This treatment approach is potentially curative and is performed by an electrophysiologist.

Patients who are not candidates for ablation, or who do not wish to undergo the procedure, can receive medications on a chronic basis. PSVT is managed with agents that slow conduction and increase refractoriness in the AV node, thereby preventing a rapid ventricular response. These include oral verapamil, diltiazem, β-blockers, or digoxin. Class Ic and III agents are used occasionally to slow conduction and increase refractoriness of the fast bypass tract to prevent triggering impulses such as premature atrial and ventricular contractions.

B.J. has had a few episodes of PSVT in the past and may be a candidate for ablation. Alternatively, because she responded to IV verapamil, oral SR verapamil could be prescribed at a dosage of 240 mg/day.

Wolff–Parkinson–White Syndrome

CASE 15-4

QUESTION 1: M.B., a 35-year-old man, presents to the ED with a chief complaint of chest palpitations for 4 hours with intermittent feeling of almost passing out (pre-syncope). M.B.'s vital signs are BP, 96/68 mm Hg; pulse, 226 beats/minute, irregular; respiratory rate, 15 breaths/minute; and temperature, 98.7°F. A rhythm strip confirms AF, with a QRS width varying from 0.08 to 0.14 seconds. To control the ventricular rate, 10 mg IV verapamil is administered over 2 minutes. Within 2 minutes of completing the infusion, VF is noted on the monitor. M.B. is defibrillated, and normal sinus rhythm is restored. A subsequent ECG demonstrates a P-R interval of 100 ms (normal, 120–200 ms) and delta waves, compatible with WPW. He relates a past medical history of many similar self-terminating episodes since he was a teenager but he has no atherosclerotic heart disease or HF. He took an unknown medication 5 years ago that decreased the occurrence of the palpitations, but he stopped taking it because of side effects. What is WPW syndrome?

WPW is a preexcitation syndrome in which there is an accessory bypass tract connecting the atria to the ventricles (Fig. 15-6). An impulse can travel down this pathway and excite the ventricle before the expected regular impulse through the AV node arrives. If there is antegrade conduction over the bypass tract while the patient is in normal sinus rhythm, the ECG will demonstrate a short P-R interval (<100 ms), a delta wave that represents a fused complex from preexcitation, and the regular QRS complex after AV conduction. PSVT and AF occur in these patients at a higher incidence than in the general population of the same age.[95] Similar to M.B., the rapid heart rate experienced during the tachycardia may cause palpitations, lightheadedness, and fatigue. When patients with WPW develop AF, there is a danger that the rapid atrial impulses will be conducted directly to the ventricle through the bypass tract, causing a rapid ventricular rate that may evolve into VF. Verapamil (like diltiazem, β-blockers, adenosine, and amiodarone) can increase this risk by increasing the effective refractory period of the AV node and indirectly reducing the effective refractory period in the bypass tract.[96]

CASE 15-4, QUESTION 2: Why did verapamil cause VF in M.B.? What therapies would be appropriate for M.B., and what drugs should be avoided?

Because M.B. had AF, the rapid atrial impulses were conducted directly down the bypass tract to the ventricle, causing VF.[97,98]

The antiarrhythmic drugs used to chemically convert patients with AF who have WPW, such as M.B., include procainamide, propafenone, flecainide, and dofetilide.[99,100] DC cardioversion is an option for more emergent conversion of AF in patients with WPW and hemodynamic instability. Radiofrequency ablation of the bypass tract is curative for many patients with WPW and is indicated for people who maintain preexcitation during exercise

---

stress testing, a shortest preexcited RR interval <250 ms, symptoms like syncope of palpitations, or preexisting structural heart disease. M.B. has symptoms associated with AF in WPW and should undergo evaluation from an cardiologist to determine if ablation is appropriate at this time.[101]

Further therapy for M.B. may not be useful at this time. However, if he has recurrent AF or other symptomatology associated with WPW, radiofrequency catheter ablation could be indicated.

CONDUCTION BLOCKS

Various arrhythmias can result from blockage of impulse conduction. These can occur above the ventricle, such as first-, second-, and third-degree (complete) AV block. Others, such as right or left bundle branch block (RBBB or LBBB) and trifascicular block, originate below the bifurcation of the His bundle. Although conduction blocks can be classified as either supraventricular or ventricular arrhythmias, they are discussed as a separate group because their mechanism of arrhythmogenesis is similar and their treatment is different from other arrhythmias.

CASE 15-5

QUESTION 1: H.T., a 63-year-old man, was admitted to the coronary care unit (CCU) 12 hours ago with an acute inferior wall MI. He has remained stable. On admission, he had developed left bundle branch block. Twelve hours later, it has changed to the rhythm strip shown in Figure 15-7 (Wenckebach or type I, second-degree AV block).

Are these rhythms potentially hazardous to H.T.? How is second-degree AV block different from first- or third-degree AV block?

H.T.'s rhythm strip initially revealed a diagnosis of LBBB. Bundle branch block occurs when the electrical impulse cannot be conducted along the left or right fascicle of the His-Purkinje system (see Fig. 15-1). In H.T., the impulse travels down the right bundle normally, and the right ventricle contracts at the normal time. The left bundle is blocked, and, therefore, the left side is depolarized from an impulse conducted from the right ventricle. This impulse must travel through atypical conduction tissues (with slower conduction), and hence the left side depolarizes later. This is revealed on the ECG by a widened QRS complex. Bundle branch blocks, particularly in the left fascicle, are associated with coronary artery disease, systemic hypertension, aortic valve stenosis, and cardiomyopathy.[102] Typically, they do not lead to clinical cardiac dysfunction on their own. Because H.T. has LBBB, he can develop complete heart block (third-degree block) if for any reason his right fascicle is damaged.

First-degree AV block usually is asymptomatic. The ECG will show P waves with a prolonged P-R interval (normal, <200 ms), but each P wave is followed by a normal QRS complex. First-degree AV block is a common finding in patients taking digoxin, verapamil, or other drugs that slow AV conduction.

Second-degree heart block consists of two types. Mobitz type I (Wenckebach) is characterized by progressive lengthening of the P-R interval with each beat until an impulse is not conducted; the cycle then starts over again. Mobitz type II (Fig. 15-8) impulse conduction is blocked in a fixed, regular pattern (e.g., 3:1 block, in which for every three P waves, only one is conducted). A major difference is that Mobitz type I can be drug induced or exacerbated by negative dromotropic drugs but not Mobitz type II.

Third-degree heart block (complete heart block) occurs when none of the impulses from the SA node are conducted to the ventricles. During third-degree block, the ventricle must develop its own pacemaker (escape rhythm), which may be too slow to provide adequate cardiac output, causing the patient to become symptomatic. A mechanical pacemaker is needed for treatment of third-degree AV block. AV blocks can be caused by drugs (β-blockers, calcium-channel blockers, digoxin), acute MI, amyloidosis, and congenital abnormalities.[102]

Atropine

CASE 15-5, QUESTION 2: How should H.T.'s heart block be treated?

H.T. is experiencing a Wenckebach rhythm, which often is transient after an inferior wall MI. As long as he is hemodynamically stable, he should be monitored closely. If his heart rate and BP drop, atropine 0.5 mg IV bolus (maximum 2 mg) or a temporary pacemaker can increase the heart rate. If the hemodynamic compromise persists, a permanent pacemaker must be inserted to initiate the impulse to control the heart rate.

VENTRICULAR ARRHYTHMIAS

Recognition and Definition

Impulses from ventricular ectopic foci or reentrant circuits generate wide, bizarre-looking QRS complexes leading to PVCs (Fig. 15-9). Three consecutive PVCs usually are defined as VT, which can be nonsustained or sustained. Ventricular flutter, VF, and TdP are other serious forms of ventricular arrhythmias. The presentation, etiology, treatment, and ion channels associated with TdP are discussed separately.

Nonsustained ventricular tachycardia (NSVT) (Fig. 15-10) commonly is defined as three or more consecutive PVCs lasting less than 30 seconds and terminating spontaneously. Sustained VT (SuVT) is defined as consecutive PVCs lasting more than 30 seconds, with a rate usually in the range of 150 to 200 beats/minute. P waves are lost in the QRS complex and are indiscernible. SuVT (Fig. 15-11) is a serious development because it can degenerate into VF. Ventricular flutter is characterized by sustained, rapid, regular ventricular beats (normal, >250 beats/minute) and usually degenerates into VF. VF (see Fig. 15-12) is characterized by irregular, disorganized, rapid beats with no identifiable P waves or QRS complexes. It is thought to be triggered by multiple reentrant wavelets in the ventricle. There is no effective cardiac output in patients with VF.[103,104]

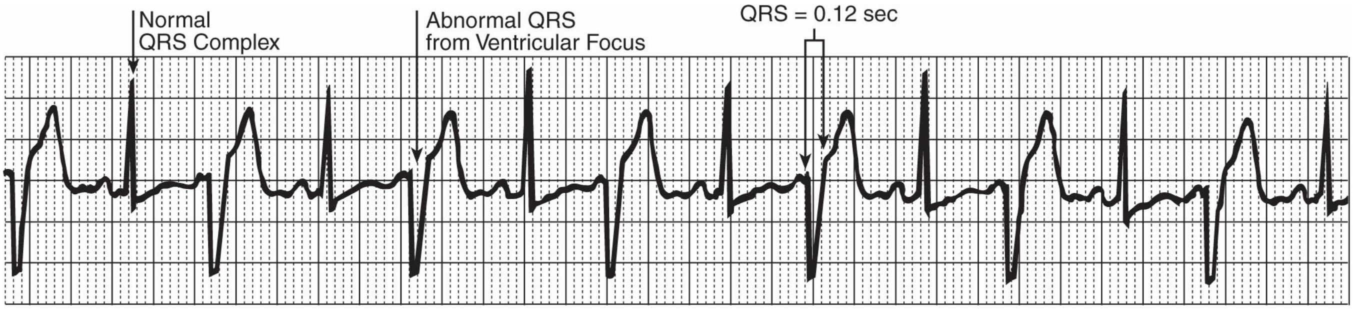

Figure 15-9 Premature ventricular contraction. Every other beat is a premature ventricular (ectopic) contraction.

Etiology

Common factors that cause ventricular arrhythmias are ischemia, the presence of organic heart disease, exercise, metabolic or electrolyte imbalance (e.g., acidosis, hypokalemia or hyperkalemia, hypomagnesemia), or drugs (digitalis, sympathomimetic amines, antiarrhythmic drugs). It is essential to identify and remove any treatable cause (e.g., metabolic or electrolyte imbalance and proarrhythmic drugs) before initiating antiarrhythmic drug therapy.

Evaluation of Life-Threatening Ventricular Arrhythmias

An episode of life-threatening ventricular arrhythmia (i.e., SuVT, TdP, VF) carries a significant risk of morbidity and mortality. Adequate documentation of the arrhythmia and its suppression by either drugs or a mechanical device are essential. Patients suspected of having, or documented to have, symptoms of a life-threatening arrhythmia (e.g., syncope, out-of-hospital cardiac arrest) should be admitted to the hospital and evaluated. At present, the European Heart Rhythm Association (EHRA)/Heart Rhythm Society (HRS)/Asia Pacific Heart Rhythm Society (APHRS) practice guidelines provided a class IIa recommendation for standard testing with a 12-lead ECG in all patients undergoing evaluation for ventricular arrhythmias, along with echocardiography (detects structural heart disease). Contrast-enhanced magnetic resonance imaging (MRI) may provide additional guidance in the management of certain forms of structural heart disease, such as dilated cardiomyopathy, hypertrophic cardiomyopathy, sarcoidosis, amyloidosis, and arrhythmogenic right ventricular cardiomyopathy.[103] Ambulatory monitoring and EP studies are two additional approaches used to evaluate the arrhythmia and the effectiveness of therapy.[103–105]

AMBULATORY MONITORING

The frequency of suspected ventricular arrhythmias determines the ambulatory monitoring device indicated for patients.[104,105] For more frequent occurrences (once daily) of arrhythmias, Holter monitoring during a 24- to 48-hour period represents the first-line ambulatory monitoring device. The patient wears a portable ECG monitoring device in a purse-like carrier, and electrodes connected to the monitor are taped to the patient’s chest. The ECG is played back in the laboratory, correlating the presence of arrhythmias with a written patient activity and symptom log. In contrast, 30-day ambulatory event recorders are selected for patients presenting with arrhythmias that occur less frequently.[104,105] The event recorder (or loop recorder) is worn constantly for 30 days and stores and saves data upon activation by the patient. Whenever a patient experiences symptoms, a switch on the recorder is depressed, resulting in storage of a record of the patient's heart rhythm at the time of the event. A telephone can transfer event recorder data for analysis. On rare occasions, cardiologists will order mobile outpatient cardiac telemetry, which is the outpatient equivalent of continuous inpatient cardiac telemetry.[104] This wearable ambulatory device can be worn for up to 6 weeks, and offers the advantage of real-time automatic detection. However, because of its high cost, many third-party payers deny coverage for patients, thereby limiting more widespread use.

ELECTROPHYSIOLOGIC STUDIES

EP studies represent another approach to evaluating ventricular arrhythmias, especially in patients with sporadic ventricular arrhythmias that may be missed by short-term monitoring.[103] EP testing serves as a diagnostic tool for evaluating drug effects, assessing the inducibility of VT, determining the risks of recurrent VT or sudden cardiac death (SCD), guiding ablation, and assessing the need for an implantable cardioverter-defibrillator (ICD).

Premature Ventricular Contractions

CASE 15-6

QUESTION 1: A.S., a 56-year-old woman, is admitted to the CCU with a diagnosis of acute anterior wall MI. Her vital signs are BP, 115/75 mm Hg; pulse, 85 beats/minute; and respiratory rate, 15 breaths/minute. Auscultation of the heart reveals an S_3 gallop. Her electrolytes include potassium (K) 3.8 mEq/L, and magnesium (Mg) 1.2 mEq/L Otherwise, her examination is within normal limits. Two days later, an echocardiogram estimates her ejection fraction to be 35% (normal, >50%). During her stay in the CCU as well as the step-down unit, multiple PVCs (15/minute) were noted on the bedside monitor. No antiarrhythmic agent was ordered. Should A.S.'s multiple PVCs be treated with a class I antiarrhythmic drug?

Occasional PVCs are a benign, natural occurrence, even in a healthy heart, and are not an indication for drug therapy. Similarly, asymptomatic simple forms of PVCs, even in patients with other cardiac disease, usually do not need treatment. However, the presence of frequent PVCs may be associated with ischemia with impaired left ventricular function.[103] Of note, it is also possible that PVCs may emerge as a result of an underlying cardiomyopathy, thereby making it difficult to prospectively determine which of these sequences apply to a given patient.

TYPE IC ANTIARRHYTHMIC AGENTS

Because PVCs are a risk factor for SCD, the National Institutes of Health launched the Cardiac Arrhythmia Suppression Trial (CAST)[106,107] to assess the benefit of PVC suppression in survivors of MI. The CAST was a prospective, randomized, placebo-controlled trial that evaluated three antiarrhythmic agents: flecainide, encainide, and moricizine (all class Ic agents). The choice of these drugs was based on results of a pilot study of 1,498 patients that showed adequate suppression of arrhythmia (PVCs) in the target population. Ten months after initiation of the study, CAST was discontinued because of excess total mortality and cardiac arrests in patients receiving flecainide and encainide. Total mortality in the flecainide and encainide groups was 8.3% compared with 3.5% in the placebo group.[106] In the moricizine group, which was reported separately in CAST II, 16 of 660 patients in the drug group died compared with 3 of 668 patients in the placebo group in the initial 2 weeks. Subsequent long-term follow-up did not show a difference between moricizine and placebo.[107] It is believed that the excessive death rate in the drug-treated groups was attributable to the proarrhythmic effect of the drugs. Because the patients enrolled in CAST were asymptomatic and at low risk for the development of arrhythmias, they were at greater risk for drug toxicity (relative to benefit). Although many issues have been raised concerning CAST, one conclusion is that patients with a recent MI and the presence of asymptomatic PVCs should not be treated with encainide, flecainide, or moricizine. Whether other class I antiarrhythmic agents will produce similar results is unknown. Thus, the decision to avoid using a class I antiarrhythmic medication to treat A.S.'s PVCs was a sound one. The proarrhythmic effects of the drug may outweigh the potential danger of PVCs at this time.

CASE 15-6, QUESTION 2: What alternatives to class I antiarrhythmic drugs should be considered for A.S.?

β-BLOCKING AGENTS

Expert consensus from the EHRA/HRS/APHRS panel suggested the use of β-blockers in patients with structural heart disease who have higher burdens of PVCs (>10,000/24 hours) or in patients without structural disease who continue to experience

---

symptomatic PVCs.[103] Despite the limited efficacy of this class of drugs with regard to PVC elimination (10%–15% achieve >90% PVC suppression), β-blockers represent the mainstay of medical suppression of PVCs. Blockade of β_1 receptors decreases automaticity in response to reduced intracellular cyclic adenosine monophosphate.[104] In addition, β-blockers exert negative chronotropic effects, lowering the resting sinus rate, along with slowing AV nodal conduction.

It is estimated that SCD accounts for 50% of all deaths among MI patients.[108] In a pooled analysis from 31 clinical trials evaluating β-blockers in MI, a 20% to 25% reduction in the risks of death and reinfarction during an average of 2 years of treatment was documented.[109] The beneficial effects of β-blockers on mortality were primarily attributed to a decrease in SCD, usually caused by arrhythmias such as VF.[110] Similarly, a meta-analysis of 28 randomized trials demonstrated that IV followed by oral β-blocker therapy resulted in a 15% to 20% decrease in the relative risks of reinfarction and cardiac arrest during the first 7 days of hospitalization for acute MI patients.[111]

The COMMIT/CCS2 (Clopidogrel and Metoprolol in Myocardial Infarction Trial/Second Chinese Cardiac Study) collaborative group assessed the effect of IV metoprolol (up to three 5-mg doses in the first 15 minutes) followed by oral metoprolol (200 mg/day in divided doses, then 200 mg once daily) or placebo on cardiovascular outcomes in 45,852 acute MI patients.[112] The two prespecified end points included the composite of death, reinfarction, or cardiac death, along with all-cause mortality. The mean duration of drug therapy was 15 days. β-Blocker therapy did not result in significant reductions in the rate of achieving the coprimary study outcomes, but five fewer episodes of VF for every 1,000 patients occurred during therapy with metoprolol (odds ratio [OR], 0.83; 95% confidence interval [CI], 0.75–0.93; $p = 0.001$). However, metoprolol-treated patients experienced 11 more episodes of cardiogenic shock for every 1,000 patients during the treatment period (OR, 1.30; 95% CI, 1.19–1.41; $p < 0.00001$).

The American College of Cardiology Foundation/American Heart Association Task Force group recommended the routine use of oral β-blocker therapy during the first 24 hours for patients who do not have contraindications (see Chapter 13, Acute Coronary Syndrome) to prevent the early occurrence of VF. Furthermore, the task force assigned a class I rating for the recommendation of long-term use of oral β-blockers for secondary prevention in patients with low ejection fraction, heart failure, or postshock.[113] Hence, in A.S. a β-blocker is an important first-line agent to initiate.

AMIODARONE

In high-risk patients with MI who are not candidates for β-blockade, alternative antiarrhythmic therapy with amiodarone can be considered.[104,105] Amiodarone is a class III antiarrhythmic agent, but also has antiadrenergic, class I, and class IV activity. However, given that cumulative exposure to this drug can result in damage to multiple organs, caution should be exercised before using it for PVC suppression.[103,105] An evaluation of amiodarone in post-MI patients with frequent PVCs (≥10/hour) or at least one run of VT was conducted in the Canadian Amiodarone Myocardial Infarction Arrhythmia Trial (CAMIAT).[114] In this trial, amiodarone significantly reduced the incidence of VF or arrhythmic death by 48.5% compared with placebo. Arrhythmic death alone was reduced by 32.6%, and all-cause mortality was reduced by 21.2%, but these differences were not statistically significant.

Similarly, the European Myocardial Infarct Amiodarone Trial (EMIAT), evaluated MI survivors with a reduced ejection fraction (<40%).[115] Amiodarone significantly reduced arrhythmic deaths by 35% compared with placebo, but this did not demonstrate any difference in mortality (13.86% with amiodarone vs. 13.72% with placebo). This suggests that amiodarone should not be used in all patients with a reduced ejection fraction after an MI, but that it could benefit patients in whom antiarrhythmic therapy is indicated. Hence, if A.S. reports problematic symptoms associated with the PVCs or develops additional risk factors for arrhythmia while on β-blockade, the first-line treatment option, antiarrhythmic therapy with amiodarone, can be given without an increased risk of overall mortality.[116,117]

If A.S. had nonsustained runs of VT instead of just PVCs, β-blockade would remain the first-line treatment option and amiodarone could similarly be considered if β-blockers are unsuccessful but in this scenario, A.S. would need to be assessed by a cardiologist to see if she would meet the criteria for receiving an ICD.[112–114]

Catheter Ablation

The EHRA/HRS/APHRS panel members recommend catheter ablation for patients with reversible left ventricular dysfunction associated with high PVC burden (>10,000/24 hours), who have failed, did not tolerate, or declined medical treatment.[103] The most commonly employed technique involves activation mapping, where electrophysiologists maneuver catheters to target the precise PVC origin in the heart, which is subsequently ablated.[104,105] Catheter ablation is not without risk, but has been shown to abolish PVCs in 74% to 100% of patients in numerous studies.[103–105]

Sustained Monomorphic Ventricular Tachycardia

TREATMENT

CASE 15-7

QUESTION 1: S.L., a 64-year-old woman, presents to the ED with a chief complaint of palpitations. Her medical history includes hypertension controlled with a diuretic, and an inferior wall MI 6 months ago. She is pale and diaphoretic but able to respond to commands. Her vital signs are BP, 95/70 mm Hg; pulse, 145 beats/minute; and respiratory rate, 10 breaths/minute. When telemetry monitoring is established, S.L. is found to be in SuVT (Fig. 15-11). S.L.'s echocardiography (6 months earlier) revealed a left ventricular ejection fraction (LVEF) of 35%.How should she be treated?

The majority of patients with SuVT have structural heart disease, and therefore require ICD placement with optimal programming. In addition to ICD placement, patients with SuVT and ischemic structural disease usually receive adjunctive therapy with antiarrhythmic drugs or undergo catheter ablation if they experience incessant SuVT. Patients with nonischemic structural disease may receive adjunctive therapy with an antiarrhythmic drug, but are less likely to undergo catheter ablation, unless they experience recurrent VT while receiving medications.[103]

The acute treatment of patients with SuVT depends on their hemodynamic stability and level of consciousness.[103] If unstable, patients should receive DC cardioversion synchronized to the QRS on the surface ECG. If the patient is conscious, but experiencing marked hypotension or excessive symptoms from SuVT, a short-acting benzodiazepine (e.g., midazolam) should be administered before undergoing cardioversion.

Antiarrhythmic Agents

To date, antiarrhythmic monotherapy has not been shown to improve mortality in patients with non-acute SuVT and structural heart disease.[117–119]

In the OPTIC study, amiodarone was superior to β-blocker monotherapy in lowering the frequency of recurrent appropriate ICD therapy (shocks) during 1-year follow-up of patients receiving

---

secondary prophylaxis.[120] The OPTIC (Optimal Pharmacological Therapy in Cardioverter Defibrillator Patients) study enrolled 412 patients with St. Jude's Medical dual-chamber ICDs; LVEF <40% who had inducible VT or VF or prior; history of SuVT, VF, or cardiac arrest; or syncope of unknown cause with VF or VT. The effect of amiodarone plus β-blocker (metoprolol, carvedilol, or bisoprolol) compared with sotalol or β-blocker alone on the primary end point, first occurrence of any shock delivered by the ICD, was assessed for a median of 359 days. One-year shock rates were 10.3%, 24.3%, and 38.5%, respectively, in amiodarone/β-blocker–treated patients, in sotalol-treated patients, and in β-blocker–treated patients. Patients receiving amiodarone combined with β-blocker had significantly lower risk of shock compared with patients receiving β-blocker monotherapy and sotalol monotherapy. Of note, adverse effects such as pulmonary toxicity, thyroid effects, and symptomatic bradycardia contributed to an 18.2% discontinuation rate for amiodarone at 1 year. However, longer term studies assessing the safety and efficacy of amiodarone for secondary prophylaxis, showed higher rates of VT recurrence and major adverse effects, compared with placebo.[121,122] Dofetilide[123] (off-label use) and the combination of mexiletine and amiodarone, have shown reductions in recurrences of SuVT in other studies.[124]

The 2010 AHA guidelines for cardiopulmonary resuscitation (CPR) and emergency cardiovascular care addressed the potential efficacy of IV antiarrhythmic drugs in stable VT patients. A class IIa rating for the use of IV procainamide was recommended by the AHA guidelines, with amiodarone (class IIb) and sotalol (class IIb) representing alternative choices of antiarrhythmic therapy for wide complex regular tachycardias.[125] IV amiodarone should be administered as a 150-mg dose for 10 minutes, followed by a 6-hour infusion at a rate of 1 mg/minute, and finally a 0.5-mg/minute infusion for 18 hours. For recurrent or resistant arrhythmias, supplemental infusions of 150 mg can be repeated every 10 minutes, up to a maximal total daily IV dose of 2.25 g. Commonly seen adverse effects associated with IV amiodarone include hypotension and bradycardia, which can be prevented by slowing the drug infusion rate.[125] Per AHA 2010 recommendations, patients with monomorphic VT who receive IV sotalol should receive a 100-mg (1.5 mg/kg) dose infused for 5 minutes.[125] IV sotalol is approximately dose-equivalent to the oral formulation, because an IV dose of 75 mg equals an 80-mg oral dose.[126] The manufacturer suggests diluting sotalol in 100 to 250 mL of 5% dextrose, normal saline, or lactated Ringer's solution, and administering the drug using a volumetric infusion pump for a 5-hour period. Common adverse effects associated with sotalol include bradycardia and hypotension. The propensity of this agent to induce TdP is covered later in this chapter. The mean elimination half-life of sotalol is 12 hours. Because it is cleared by the kidneys, its clearance is reduced and its half-life prolonged in patients with renal dysfunction. Consequently, patients receiving sotalol should receive continuous BP, heart rate, and ECG monitoring. Patients who experience excessive QT prolongation while on sotalol should receive lower doses or the drug should be discontinued.

Implantable Cardiac Defibrillators (ICDs)

CASE 15-7, QUESTION 2: On hospital day 2, S.L. experiences a run of VT lasting about 2 minutes. The cardiology consult service has recommended placement of an ICD. What is an ICD, and how does it work?

Transvenous ICDs are devices implanted under the skin with wires or patches that are advanced or attached so they are in direct contact with the ventricular myocardium. The ICD is composed of a pulse generator, sensing and pacing electrodes, and defibrillation coils. The pulse generator consists of a microprocessor, a memory component capable of storing ECG data, a high-voltage capacitor, and a battery. The microprocessor controls the analysis of cardiac rhythm and delivery of therapy. An electrode is usually placed at the endocardium of the right ventricular apex, but in some rare cases, it is surgically placed on the epicardium. Patients with dual-chamber ICDs have a second electrode placed in the right atrial appendage. Biventricular ICDs have an additional electrode placed surgically on the epicardium of the left ventricle, or more commonly, placed transcutaneously in a branch off of the coronary sinus. Defibrillation coils are positioned on the right ventricular electrode at the level of the right ventricle and the superior vena cava. In most ICD systems, biphasic defibrillation current flows from the distal defibrillation coil to the pulse generator and to the proximal defibrillation coil.[127]

Since 2012, numerous advancements in ICD technology have occurred: (a) development of longer-lasting batteries (up to 12 years for Boston Scientific models); (b) emergence of quadripolar leads to optimize therapeutic efficacy through improved device programming; (c) development of subcutaneous ICDs (s-ICDs); and (d) development of MRI-safe ICDs (available in Europe).[128] The s-ICD system (model SQ-RX 1010, Cameron Health, Inc., San Clemente, California) consists of a subcutaneous pulse generator and a single subcutaneous electrode, comprised of sensing and defibrillating components.[129] The pulse generator is usually placed in the subcutaneous pocket created over the fifth intercostal space between the mid and anterior axillary lines. Placement of the subcutaneous lead is parallel to the left side of the sternum, with its upper pole situated at the level of the sternal notch and the lower electrode positioned beneath the level of the xiphoid process. Some of the advantages of using the s-ICD system include elimination of potential adverse events associated with venous access, minimal physical stress on leads associated with cardiac motion, and relative ease of device extraction. However, unlike transvenous ICDs, the currently marketed s-ICD has a larger pulse generator, along with having less data on long-term performance. Furthermore, the current s-ICD does not provide antitachycardia pacing for VT.[129] Multiple clinical trials have proved the superiority of ICD treatment over antiarrhythmic therapy for the secondary prevention of SCD. On the basis of evidence from numerous clinical trials of primary and secondary prevention of SCD, the American College of Cardiology/American Heart Association/Heart Rhythm Society 2012 guidelines for device-based therapy of cardiac rhythm abnormalities assigned a class Ia rating for ICD implantation in seven groups of patients. ICD therapy is indicated for (a) survivors of cardiac arrest caused by VF or hemodynamically unstable sustained VT (level of evidence [LOE] A); (b) patients with LVEF equal to or less than 35% caused by a prior MI who are at least 40 days after the event and are in NYHA functional class II or III (LOE A); (c) patients with LVEF equal to or less than 30% caused by prior MI who are at least 40 days after the event and are in NYHA functional class I (LOE A); (d) patients experiencing spontaneous SuVT in conjunction with structural heart disease, regardless of hemodynamic stability (LOE B); (e) hemodynamically compromised patients with electrophysiology study–induced SuVT or VF associated with syncope of undetermined origin; (f) patients with LVEF less than or equal to 35% associated with nonischemic dilated cardiomyopathy and are in NYHA functional class II or III (LOE B); and (g) patients with LVEF less than or equal to 40% in conjunction with NSVT secondary to prior myocardial infarction, who experience SuVT or inducible VF at EP study (LOE B).[130]

Although ICDs have been shown to improve survival in select patient populations, the benefit may be offset by diminished quality

of life associated with painful shocks, increased mortality compared with ICD patients who do not require shocks, and incomplete protection from the occurrence of

SCD (5% of patients fail to respond).[120,131,132] In recent years, investigators have examined various approaches to reducing the frequency of ICD shocks. Antiarrhythmic medications and prophylactic catheter ablation have been shown to reduce the incidence of ICD firing.[120,131,132] The EHRA/HRS/APHRS taskforce group assigned a class IIa rating for the strategies of programming ICDs to a delayed VT detection interval and a high VF detection rate in patients requiring primary prophylaxis.[103]

Defibrillation threshold is classified as the minimum amount of energy needed to result in successful defibrillation of the heart and restoration of normal sinus rhythm.[133] It is important for clinicians to be aware that antiarrhythmic agents have been associated with increases (amiodarone) or reductions (dofetilide) in ventricular fibrillation thresholds.[133–135]

Clearly, S.L. should have an ICD implanted. It is her best chance for prolonging long-term survival. Depending on the number of times the machine discharges per month and the patient's response, adjunctive antiarrhythmic drugs or prophylactic ablation may be needed, along with optimizing ICD programming.

Amiodarone

CASE 15-7, QUESTION 3: S.L.'s cardiologist would like to start amiodarone as adjunctive therapy because S.L. has expressed concern about the number of ICD discharges that may occur after ICD placement. If S.L. is to be treated with amiodarone, how should it be initiated and monitored?

Amiodarone exhibits properties of classes I, II, III, and IV antiarrhythmic agents. Although it has class II effects on the heart, amiodarone is virtually devoid of antiadrenergic effects outside the heart and is not contraindicated in patients with asthma. The antiadrenergic effects arise from inhibition of adenylate cyclase, the enzyme that catalyzes production of the second-messenger product cyclic adenosine monophosphate. Amiodarone can also cause a reduction in β_1-receptor density.[136,137]

Because of the extremely long half-life of amiodarone, loading doses are used to accelerate the onset of drug effect. The OPTIC trial used a loading dose of oral amiodarone 400 mg, given twice daily for 2 weeks, followed by a daily dose of 400 mg for the next 4 weeks, and a daily maintenance dose of 200 mg thereafter.[120] Although a concentration–effect relationship is hard to determine for amiodarone, levels greater than 2.5 mg/L are associated with an increased incidence of adverse effects.[138]

Amiodarone has many serious adverse effects involving a variety of organ systems, the most serious and life-threatening of which is pulmonary toxicity. Amiodarone-induced pulmonary toxicity (AIPT) has been shown to account for 11% of the sum total of all reported adverse events associated with this agent.[139] AIPT presents as an acute process or a chronic condition that develops several months after starting amiodarone therapy. The pathophysiologic mechanism for AIPT has not been fully elucidated, but may involve: (a) heightened extracellular expression of β-hexosaminidase; (b) imbalance between T-helper 1 and 2 cells, leading to a maladaptive immune response; (c) increased tumor necrosis factor-α activity; and (d) angiotensin-mediated apoptotic effects of amiodarone on alveolar epithelial cells. It has been suggested that higher doses of amiodarone, older age, and preexisting pulmonary disease may predispose patients to developing AIPT. However, AIPT has been shown to occur after patients received low doses of amiodarone (200 mg/day). Manifestations of chronic AIPT include cough, dyspnea, impaired diffusion capacity of carbon monoxide, infiltrates on chest radiograph, weight loss, and fever. In contrast, patients presenting with acute AIPT experience rapid decline in respiratory function, potentially culminating in the development of acute respiratory distress syndrome (ARDS) with alveolar opacities. Given the prolonged half-life of amiodarone, symptom resolution will be a slow process for patients with AIPT. Patients presenting with marked radiographic opacities and hypoxemia may need to receive prednisone 40 to 60 mg daily for several months. Mortality rates for patients with AIPT have been shown to approach 10%, with higher mortality rates seen in patients requiring hospitalization (20%–30%) or who develop ARDS (50%).[139]

A baseline chest radiograph and pulmonary function tests (diffusion capacity in particular) are recommended by the manufacturer.[140] The chest radiograph should be repeated at 3- to 6-month intervals, and patients should be specifically questioned about pulmonary symptoms because early detection can decrease the extent of lung damage.[140]

Liver toxicity can range from an asymptomatic elevation of transaminases (2–4 times normal) to fulminant hepatitis. The mean latent period between the start of amiodarone therapy and evidence of liver injury is 10 months (onset can be as short as 3–4 days), but with rapid IV loading of amiodarone, a Reye's-like fulminant hepatitis can occur as early as 1 day after starting therapy, most likely caused by the IV vehicle polysorbate-80. The precise mechanism of amiodarone-induced hepatotoxicity has not been fully elucidated. However, higher doses and prolonged drug use appear to place patients at higher risk of experiencing hepatotoxic effects of amiodarone. Thus liver enzymes should be monitored at baseline, 1, 3, 6 months, and semiannually afterward.[140,141] The most common GI complaints are nausea, anorexia, and constipation, which occur in 25% of patients receiving amiodarone.[140]

Both hypothyroidism and hyperthyroidism have been reported, although hypothyroidism is more common. The thyroid complications are a consequence of amiodarone's large iodine content and its ability to block the peripheral conversion of thyroxine (T_4) to triiodothyronine (T_3). In addition, amiodarone and its metabolite, desethylamiodarone, appear to be directly cytotoxic to the thyroid gland.[142]

Recent reports have indicated that photosensitive eruptions occur in 7% of amiodarone recipients.[143] Classical presentations of amiodarone photosensitivity involve a burning and tingling sensation in sun-exposed skin with accompanying erythema. Approximately 1% to 2% of patients receiving amiodarone for long-term use develop blue-gray pigmentation on sun-exposed skin. Resolution of amiodarone-associated photo-induced pigmentation may take up to 2 years, with gradual fading of skin discoloration.[143] In recent years, amiodarone-associated optic neuropathy has been highlighted in multiple case reports. A review of amiodarone-associated optic neuropathy (January 1993–May 2011) revealed a total of 214 cases from the FDA's Adverse Event Reporting System, 59 published cases, and 23 cases from clinical trials.[144] On average, patients received amiodarone for 9 months (range 1–84 months) before experiencing vision loss. In 20% of cases, patients progressed to legal blindness in at least one eye. Other bothersome side effects are corneal deposits (usually asymptomatic), exacerbation of heart failure, and central nervous system effects that include ataxia, tremor, dizziness, and peripheral neuropathy. Other than eye examination and pulmonary function tests, which should be repeated when the patient is symptomatic, other tests should be repeated every 6 months (thyroid and liver function) or annually (chest x-rays) for routine monitoring.[140,144] Amiodarone also blocks multiple cytochrome P-450 enzyme systems and P-glycoprotein pumps, resulting in clinically significant drug interactions.

Torsades de Pointes

PROARRHYTHMIC EFFECTS OF ANTIARRHYTHMIC DRUGS AND CLINICAL PRESENTATION

CASE 15-8

QUESTION 1: L.G. is a 69-year-old woman who is taking sotalol 80 mg twice daily for a previous episode of SuVT. L.G. was admitted to the hospital 3 days ago for altered mental status. She is also taking oral citalopram 40 mg every morning for major depressive disorder. At baseline, her QTc interval was 400 ms, and her CrCl was 50 mL/minute. Other laboratory values are as follows:

Sodium, 139 mmol/L
Chloride, 108 mmol/L
Potassium, 4.0 mmol/L
CO_2, 22 mmol/L
Blood urea nitrogen (BUN), 32 mg/dL
Serum creatinine, 1.5 mg/dL
Random glucose, 102 mg/dL
Calcium, 8.5 mg/dL
Albumin, 2.9 g/dL
Phosphorous, 3.3 mg/dL

Today, her ECG reveals a QT_c interval of 502 ms and TdP, with a ventricular rate of 110 beats/minute. What is QTc interval prolongation? Why does QTc interval prolongation indicate an increased risk of TdP? Could an antiarrhythmic agent such as sotalol cause this arrhythmia? How does CrCl affect this?

The QT interval denotes ventricular depolarization (the QRS complex in the cardiac cycle) and repolarization (from the end of the QRS complex to the end of the T wave). Certain ion channels in phases 2 and 3 of the action potential are vital in determining the QT interval (Fig. 15-1). An abnormal increase in ventricular repolarization increases the risk of TdP. TdP is defined as a rapid polymorphic VT preceded by QTc interval prolongation. TdP can degenerate into VF and as such can be life threatening (Fig. 15-13).[145]

Because there is tremendous variability in the QT interval resulting from changes in heart rate, the QT is frequently corrected for heart rate (QTc interval). Several correction formulas for the QT interval exist and give similar results at most heart rates. The most common correction formula uses QT and R-R intervals measured in seconds as follows: ($QTc = QT/[R\text{-}R^{0.5}]$). However, overcorrection of the QT interval may occur in persons with elevated heart rates (>85 beats/minute).[146,147] The Fridericia correction ($QT_c = QT/[R\text{-}R^{1/3}]$) represents an alternative correction method for patients with heart rates exceeding 85 beats/minute.

The ACC and AHA recently addressed the issue of the prevention of TdP in hospital settings. They stated that each 10-ms increase in QT_c confers an additional 5% to 7% TdP risk in patients with congenital long QT syndrome (LQTS).[147] The International Conference on Harmonization stated that prolongation of QT_c interval by more than 30 ms and in excess of 60 ms should be classified as a potential adverse effect and a definite adverse effect, respectively.[148]

Class Ia and class III antiarrhythmic agents have been shown to induce TdP in numerous literature reports.[149] Of note, class Ia antiarrhythmic agents do not exhibit dose-dependent association with TdP, whereas the incidence of TdP does appear to be dose-related with class III antiarrhythmic agents. QT prolongation associated with the use of class Ia antiarrhythmic agents is likely the result of blockade of outward potassium channels, but it is offset by concomitant blockade of inward sodium channels at increased drug concentrations.[150] TdP induced by class III antiarrhythmic agents arises from prolonged repolarization and cardiac refractoriness. All class III antiarrhythmic agents have been implicated in cases of TdP. A recent review of the US FDA Adverse Event Reporting System (AERS) database showed the following number of TdP cases that occurred during a 2-year time period: dronedarone (37), amiodarone (29), dofetilide (12), and sotalol (4).[150] Incidence rates could not be calculated because true denominators were not available and all events were self-reported. However, given the considerably larger prescriptive volume of amiodarone, this agent appears to have a relatively low propensity for inducing TdP.

Class Ic antiarrhythmic agents do not exert significant effects on repolarization, and therefore have rarely been shown to induce TdP. To date, eight cases of flecainide-induced TdP have been published, along with one report of propafenone-associated TdP.[151–153]

Sotalol is known to cause QTc interval prolongation in a dose-dependent manner. Total daily doses of 160, 320, 480, and >640 mg gave patients a steady-state QTc interval of 467, 473, 483, and 512 milliseconds, and the incidence of TdP was 0.5%, 1.6%, 4.4%, and 5.8%, respectively.[154]

It is likely that L.G.'s reduced renal function put her at high risk for sotalol accumulation and accentuated QTc interval prolongation. In patients with a CrCl greater than 60 mL/minute, the sotalol dose of 80 mg twice daily is appropriate, but in patients like L.G. with a CrCl less than 40 to 60 mL/minute, the manufacturer-recommended dose should be 80 mg daily or 40 mg twice daily owing to sotalol's predominant renal clearance.

Figure 15-13 Torsades de pointes.

CASE 15-8, QUESTION 2: What transient conditions or other disorders can increase the risk of TdP in patients on class Ia or III antiarrhythmic agents?

Hypokalemia, hypomagnesemia, hypocalcemia (rare cases of TdP), concurrent use of more than one QT-prolonging drug, advanced age, female sex, heart disease (heart failure or myocardial infarction), treatment with diuretics, impaired hepatic drug metabolism, and bradycardia are important risk factors for TdP in hospitalized patients.[147] Hypokalemia may prolong QT interval by modifying the function of the inwardly rectifying potassium channel, resulting in heterogeneity and dispersion of repolarization. Prolonged ventricular cycle length can assume the form of complete AV block, sinus bradycardia, or a rhythm in which long cycles may progress to arrhythmogenic EAD.

Congenital LQTS occurs in 1 in 2,500 individuals, and is a channelopathy associated with mutations identified in genes encoding voltage-gated sodium and potassium channels.[147] Since 1995, approximately 1,000 individual LQTS-causing mutations have been detected in 12 distinct LQTS-susceptibility genes. The LQTS-susceptibility genes KCNQ1 (encoded I_{Ks} α-subunit), KCNH2 (encoded I_{Kr} α-subunit), and SCN5A (encoded Nav1.5 α-subunit) account for nearly 75% of all congenital LQTS cases.

Because L.G. did not have a family history of hereditary LQTS but was being treated with sotalol (an agent known to be associated with TdP) in renal dysfunction, it can be assumed that sotalol therapy was responsible for her arrhythmia.

CASE 15-8, QUESTION 3: Which nonantiarrhythmic agents cause TdP? What is the mechanism of TdP initiation in this situation?

PROARRHYTHMIC EFFECTS OF NONANTIARRHYTHMIC AGENTS

Nonantiarrhythmic agents can also exhibit potassium-channel inhibitory properties and can prolong the QTc interval. Most of these drugs, including arsenic trioxide, macrolide antibiotics, fluoroquinolones, azole antifungals, methadone, antidepressants, organophosphorus compounds, and antipsychotics, cause QTc interval prolongation by inhibiting the inwardly rectifying potassium ion channel, just like quinidine and sotalol.[155] Moreover, toxic concentrations of nonantiarrhythmic drugs can induce TdP as a result of large doses, impaired kidney or liver function, or other drug therapy that interferes with metabolism of nonantiarrhythmic drugs.

On August 24, 2011, the US FDA sent out an alert to health care providers and patients on new dosing recommendations for citalopram due to concerns of QT_c interval prolongation and TdP when using this agent at higher doses.[156] Key recommendations included: (1) prescribing citalopram at a dose of ≤20 mg/day for patients older than 60 years of age (also, in patients <60 years with hepatic impairment or taking cimetidine); and (2) prescribing citalopram at a dose of ≤40 mg/day for younger patients. Hasnain and associates recently conducted a comprehensive review of published literature on QT_c interval prolongation and/or TdP risk associated with antidepressants and second-generation antipsychotics (SGAPs).[157] The authors identified the highest number (16) of case reports implicating citalopram, relative to other antidepressants, including fluoxetine (9), escitalopram (6), venlafaxine (5), and sertraline (2). Case report material revealed quetiapine as the SGAP with the largest number of QT_c interval prolongation and/or TdP cases (16), followed by ziprasidone (13), risperidone (13), amisulpride, olanzapine (6), and clozapine (5). The authors of the review noted that patients had at least one additional risk factor for QT_c interval prolongation in 92% of the reports. In addition, they acknowledged that the information yielded by case reports did not allow for comparison between drugs and generalization to clinical practice.

During the past two decades, multiple case reports of methadone-induced TdP have been published. Guidelines recommend QT interval monitoring, but some experts have questioned the necessity of screening patients.[158] Kao et al.[158] reviewed the FDA Adverse Event Reporting System (FAERS) database for QT_c interval prolongation or TdP events linked with methadone compared to other agents, including antiarrhythmic drugs and other opioids. Between 2000 and 2011, the three most commonly implicated drugs included dofetilide (359 cases), methadone (211), and sotalol (119). The authors acknowledged limitations of their analysis (voluntary and selective reporting to FAERS, along with the inability to determine incidence rates), but suggested that a REMS specific to methadone may be warranted, in order to lower the risk of TdP. The recent emergence of methadone-associated TdP could be attributable to escalating doses used in recent years, given the preponderance of published cases of patients receiving very high doses of this agent.[159]

Currently, the utility of published cardiac risk data on anti-infective agents is limited, owing to underreporting, failure to completely eliminate contributory confounding variables (cardiac disease, electrolyte abnormalities, use of other QT-prolonging drugs), and the retrospective nature of some postmarketing studies.[148] However, the propensity of antimicrobial agents to induce QT prolongation appears to be especially marked with macrolide antibiotics.[160] All of the commercially available antifungal agents have been shown to induce TdP and QT_c prolongation, with a larger number of cases attributed to fluconazole, followed by voriconazole.[160] Among the marketed quinolones in the United States, ciprofloxacin appears to display the lowest potential for causing TdP.[161]

A list of nonantiarrhythmic agents implicated in causing QTc interval prolongation and known pharmacokinetic drug interaction increasing the blood concentrations of these drugs is given in Table 15-6.

Because L.G. was taking citalopram in combination with sotalol, it is likely that QTc-prolonging effects resulting from concomitant use contributed to the development of TdP.

TREATMENT

CASE 15-8, QUESTION 4: How should TdP be treated? What treatments should be considered for L.G.?

If the patient is significantly hemodynamically compromised (frequently associated with a ventricular rate >150 beats/minute and unconsciousness) while in TdP, electrical cardioversion is the therapy of choice and should be given immediately. Stepwise increasing shocks of 100 to 200, 300, and 360 J (monophasic energy) can be tried if earlier shocks are unsuccessful.

Magnesium

In a hemodynamically stable patient, magnesium is frequently considered the drug of choice to restore normal sinus rhythm. It benefits patients whether they have hypomagnesemia or normal serum magnesium levels. However, magnesium is not effective for patients with polymorphic VT without TdP and with normal QT intervals. Before administering magnesium, potassium levels should be supplemented to the high normal range of 4.5 to 5.0 mmol/L.[155] A common magnesium regimen is 2 g given for 60 seconds through the IV route, followed by an infusion of 2 to 4 mg/minute.[155] The exact mechanism of action for magnesium in TdP is not known, but it reduces the occurrence of triggered activity such as EAD. In addition, magnesium blocks L-type calcium channels in the membrane, and may stabilize the membrane gradient through activation of the sodium-potassium ATPase.[161]

Table 15-6

Nonantiarrhythmic Agents with Known Torsades de Pointes Risk[a]

Drug Class	Agent	Drugs That Increase Blood Concentrations of These QTc Interval–Prolonging Drugs
Anesthetic, general	Propofol, sevoflurane	
Antibiotics: macrolides	Azithromycin, clarithromycin, erythromycin (lactobionate and base)	
Antibiotics: fluoroquinolones	Ciprofloxacin, levofloxacin, moxifloxacin	
Antibiotics: other	Pentamidine isethionate	
Anti-cancer	Arsenic trioxide, vandetanib	
Antidepressants	Citalopram, Escitalopram	CYP3A4 or 2C19 inhibitors
Antiemetics	Chlorpromazine, droperidol, ondansetron	CYP3A4 (primary for ondansetron), 1A2 (primary for chlorpromazine), or 2D6 inhibitors
Antifungals	Fluconazole	
Antimalarials	Chloroquine, halofantrine	Cimetidine (chloroquine), CYP3A4 inhibitors (halofantrine)
Antipsychotics	Haloperidol, pimozide, thioridazine	CYP2D6 (thioridazine) or 3A4 (pimozide) inhibitors
Cholinesterase inhibitors	Donepezil	CYP3A4 or 2D6 inhibitors
Narcotics	Methadone	CYP3A4, 2B6, and 2C19 inhibitors
Phosphodiesterase 3 inhibitor	Anagrelide, cilostazol	CYP1A2 (anagrelide), 3A4 (primary for cilostazol), or 2C19 inhibitors

[a] An up-to-date list can be found at http://www.crediblemeds.org/everyone/

Other Treatment Options for TdP

Numerous other strategies have been utilized for patients who fail to respond adequately to standard therapeutic approaches, including calcium-channel blockers, αblockers, potassium-channel openers, lidocaine, and mexiletine.[162] However, the evidence supporting these alternative agents is not compelling enough to classify them as first-line options for abolishing TdP.

Cardio acceleration with isoproterenol (1–4 mcg/minute) or cardiac pacing has also been shown to be beneficial.[163–165] As described previously, the ability of sotalol, quinidine, and N-acetylprocainamide to prolong the APD is diminished at faster heart rates (reverse use dependence).[166] The more the inwardly rectifying potassium channels are activated, the less susceptible the channels are to inhibition by potassium-channel blocking drugs.

Transvenous pacing has been shown to be of some use in abolishing refractory TdP.[163] Before adjusting the ventricular rate to suppress ectopic ventricular beats, it is essential to ensure proper catheter placement and cardiac capture. In general, ventricular rates of 90 to 110 beats/minute can usually eliminate ventricular ectopy, but some patients may require rates as high as 140 beats/minute. Once control of TdP has been attained, the pacing rate can be gradually decreased to the lowest paced rate that suppresses further ectopy and dysrhythmia.

Because L.G. is hemodynamically stable, a bolus injection of 2 g of magnesium should be administered over 1 minute, followed by an infusion administered at a rate of 2 to 4 mg/minute. In addition, she should receive potassium supplementation (infusion) to achieve a potassium level of 4.5 to 5.0 mmol/L. If the arrhythmia recurs, cardiac pacing should be used.

CARDIOPULMONARY ARREST

Cardiopulmonary Resuscitation

Cardiac arrest from VF, pulseless VT, pulseless electrical activity (PEA), and asystole are life-threatening emergencies. Table 15-7[167–173] reviews commonly used drugs for these indications, and Figure 15-14 highlights key features of the management of pulseless arrest in the 2010 AHA Guidelines (2015 update to be released in October 2015). This section will review important aspects of therapy and will give clinical pearls, but the reader should also review the national consensus source document for these disorders, which includes more detail than can be given here.[167]

Treatment

CASE 15-9

QUESTION 1: M.N., a 52-year-old man, is visiting his wife, who is hospitalized for pneumonia. His past medical history is significant for hypertension and type 2 diabetes mellitus. He goes into the bathroom and 2 minutes later his wife hears a dull thud. She calls out for her husband, but he does not respond. After an additional 2 minutes, health care workers open the bathroom door and find M.N. unresponsive and pulseless. CPR is initiated and a code blue is called. The ECG shows VF (Fig. 15-12), and there is no BP. In addition to CPR, what initial therapy is available?

Determining the underlying rhythm disturbance is important because it directs health care workers to follow the Advanced Cardiac Life Support (ACLS) algorithm for pulseless VT or VF (Fig. 15-14). This algorithm calls for electrical defibrillation first, but other clinicians should work to establish IV access in case defibrillation fails.[167]

EXTERNAL DEFIBRILLATION

Although commercially available manual defibrillators provide monophasic or biphasic waveform shocks, the biphasic defibrillator has become the preferred device owing to its high first-shock efficacy.[167] Most commercially available biphasic defibrillators display the device-specific energy dose range that should be used. However, if a health care provider operating a manual biphasic defibrillator is uncertain of the effective energy dose to terminate VF, using the maximal shock energy setting available is preferred. For second and subsequent shocks delivered by manual biphasic defibrillators, the same or higher energies should be used. For first and subsequent shocks, a shock of 360 J should be delivered if a monophasic defibrillator is used to terminate VF.

Table 15-7

Commonly Used Drugs in Cardiac Arrest

Drug	Formulation	Dosage/Administration	Rationale/Indications	Comments
Amiodarone	50 mg/mL Vials: 3, 9, 18 mL	300 mg diluted in 20–30 mL D5W or NS; additional 150 mg (diluted solution) can be given for recurrent or refractory VT or VF.	Exhibits antiadrenergic properties and blocks sodium, potassium, and calcium channels. First-line antiarrhythmic for pulseless VT and VF.	Excipients (polysorbate 80 and benzyl alcohol) can induce hypotension. Failing to dilute can induce phlebitis.
Epinephrine	0.1 mg/mL (1:10,000) or 1 mg/mL (1:1,000)	10 mL of a 1:10,000 solution of epinephrine (1 mg; dilute 1:1,000 solution in 0.9% sodium chloride) every 3–5 minutes.	Increases coronary sinus perfusion pressure through α_1 stimulation. Indicated in pulseless VT, VF, asystole, and PEA.	If administered through peripheral catheter, need to flush the line to get drug into the central compartment.
Vasopressin	20 units/mL Vials: 0.5, 1, 10 mL	40-unit dose can be used to replace first or second dose of epinephrine	Increases coronary sinus perfusion pressure through vasopressin receptor stimulation.	Vasopressin is an acceptable alternative to epinephrine, may work better if time

			Indicated in pulseless VT, VF, asystole, and PEA.	from cardiac arrest to ACLS is delayed.

ACLS, Advanced Cardiac Life Support; D5W, 5% dextrose in water; NS, normal saline; PEA, pulseless electrical activity; VF, ventricular fibrillation; VT, ventricular tachycardia.

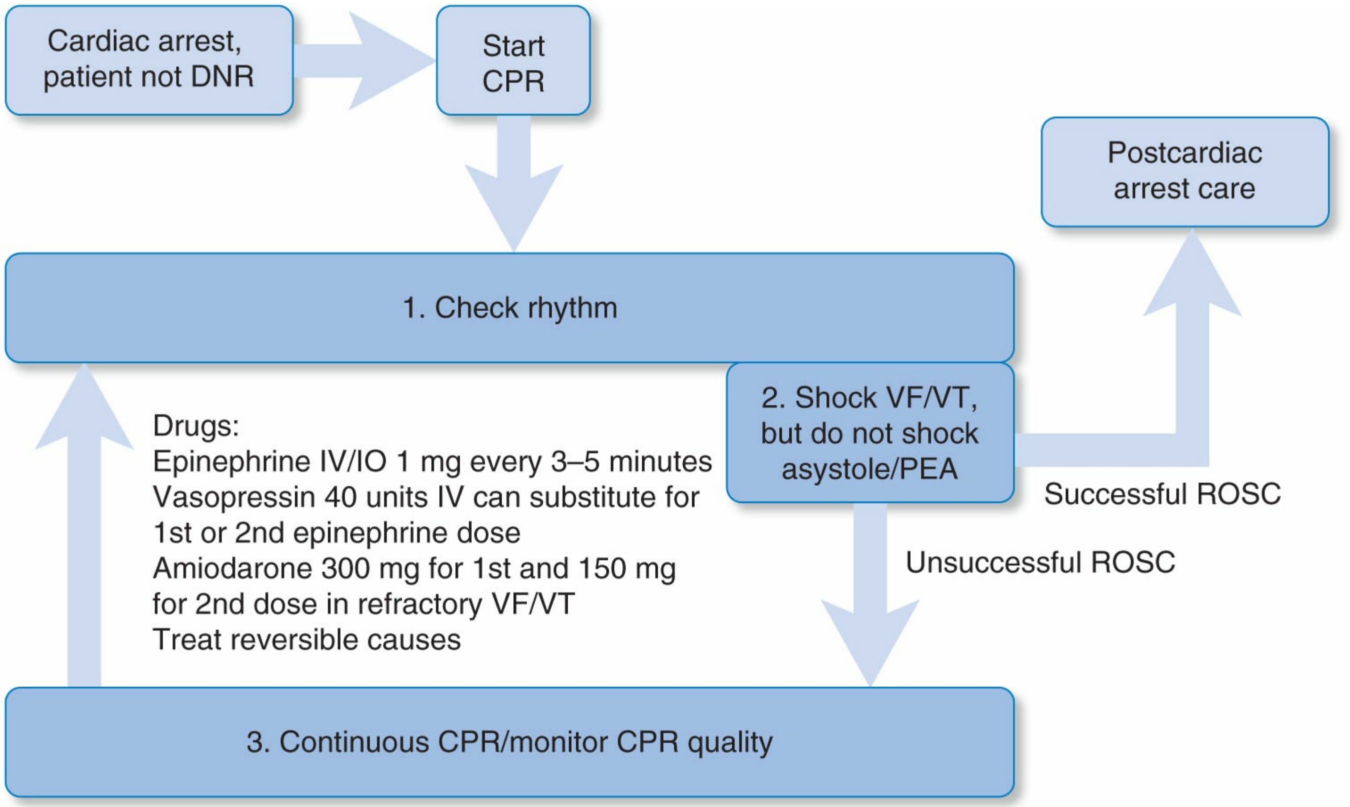
CASE 15-9, QUESTION 2: The initial shock fails to cause a return of spontaneous circulation in M.N. An IV catheter is established in a peripheral arm vein. The algorithm now calls for epinephrine or vasopressin, but which one should be used?

EPINEPHRINE AND VASOPRESSIN

Although epinephrine stimulates β_1-, β_2-, and α_1-adrenergic receptors, it is the α_1-adrenoceptor effects that are most closely associated with efficacy in VF or pulseless VT.[167] Applying α_1-adrenoceptor stimulation increases systemic vascular resistance (via vasoconstriction), which elevates coronary perfusion pressure. This increase in coronary perfusion pressure is most likely the key to enhancing the return of spontaneous circulation after subsequent electrical defibrillation. Epinephrine may convert fine VF to a coarse variety that may be more amenable to defibrillation.

The recommended dose of epinephrine is 1 mg (10 mL of a 1:10,000 dilution; refer to Table 15-7) given by IV push. The dosage can be repeated at 3- to 5-minute intervals during resuscitation. If the drug is given IV through a peripheral catheter, which in this case includes a peripherally inserted central catheter, then a 20-mL flush with normal saline is recommended to ensure delivery into the central compartment. Only chest compressions cause blood circulation in VF or pulseless VT, so movement of drugs from the periphery to the heart (where the benefit will occur) is severely impaired.

Vasopressin is an exogenously administered antidiuretic hormone. In supraphysiologic doses, vasopressin stimulates V1 receptors and causes peripheral vasoconstriction. Vasopressin use during CPR causes intense vasoconstriction to the skin, skeletal muscle, intestine, and fat, with much less constriction of coronary vascular beds. Cerebral and renal vasodilation occurs as well.



Cardiac arrest, patient not DNR
Start CPR
Postcardiac arrest care
1. Check rhythm
2. Shock VF/VT, but do not shock asystole/PEA
Successful ROSC
Unsuccessful ROSC
Drugs:
Epinephrine IV/IO 1 mg every 3–5 minutes
Vasopressin 40 units IV can substitute for 1st or 2nd epinephrine dose
Amiodarone 300 mg for 1st and 150 mg for 2nd dose in refractory VF/VT
Treat reversible causes
3. Continuous CPR/monitor CPR quality

Figure 15-14 Cardiac arrest treatment algorithm. CPR, cardiopulmonary resuscitation; DNR, do not resuscitate; IO, intraosseous; IV, intravenous; PEA, pulseless electrical activity; ROSC, restoration of spontaneous circulation; VF, ventricular fibrillation; VT, ventricular tachycardia.

The results of a prospective, randomized, controlled, multicenter study (n = 1,186) that enrolled out-of-hospital cardiac arrest patients who presented with VF, PEA, or asystole showed that administration of vasopressin as adjunctive therapy resulted in similar survival to hospital admission rates (primary outcome measure) compared with adjunctive epinephrine therapy.[168] In this study, patients were randomly assigned to receive two ampules of 40 international units of vasopressin or two ampules of 1 mg of epinephrine. The second dose of vasopressor was injected if spontaneous restoration of circulation did not occur within 3 minutes after the first injection of the drug. If the absence of spontaneous circulation persisted, the physician administering CPR had the option of injecting epinephrine. The reported survival rates were similar between the two treatment groups for both patients with PEA and those with VF.

An in-hospital study of 200 cardiac arrest patients (initial rhythm: 16%–20% VF, 3% VT, 41%–54% PEA, 27%–34% asystole) showed no difference in 1-hour or hospital discharge survival for vasopressin 40 units versus epinephrine 1 mg.[169] Similarly, a meta-analysis of five randomized trials showed no survival advantage of vasopressin treatment versus epinephrine treatment at the time of hospital discharge or 24 hours after treatment.[170]

Since the publication of the 2010 ACLS guideline, some study investigators have focused on assessing long-term outcomes in out-of-hospital cardiac arrest patients.[174,175] Hagihara and associates[174] showed that out-of-hospital cardiac arrest patients who received epinephrine prior to hospital arrival had lower rates of 1-month survival and 1-month survival with favorable neurologic function, compared to patients who did not receive epinephrine ($p < 0.001$). Similarly, Goto et al.[175] showed significantly lower rates of 1-month survival and 1-month survival with favorable neurologic outcomes in out-of-hospital cardiac arrest patients with shockable rhythm, who received epinephrine before hospital arrival, relative to patients who did not receive epinephrine ($p < 0.001$).

On the basis of these trials, it would be reasonable to use a single dose of vasopressin 40 units as an alternative to either the first or second dose of epinephrine 1 mg in the treatment of VF (or pulseless VT).

CASE 15-9, QUESTION 3: One of the physicians delivering ACLS for M.N. wants to initiate corticosteroid therapy. What is the evidence supporting the use of corticosteroid therapy in patients experiencing cardiac arrest?

A randomized, double-blind, placebo-controlled, parallel-group trial performed by Mentzelopoulos et al.[176] assessed the impact of using two different strategies for managing in-hospital cardiac arrest patients on: (a) survival to hospital discharge with favorable neurologic status; and (b) probability for return of spontaneous circulation for 20 minutes or longer. One group of patients received epinephrine (1 mg/CPR cycle), vasopressin (20 IU/CPR cycle), and corticosteroid therapy (methylprednisolone 40 mg during first CPR cycle, then hydrocortisone 300 mg/day [for post-resuscitation shock] for up to 7 days, followed by taper). The control group received epinephrine in combination with saline placebo. Epinephrine–vasopressin–corticosteroid recipients exhibited superior rates of probability for return of spontaneous circulation for ≥20 minutes (83.9% vs. 65.9%; OR, 2.98; 95% CI, 1.39–6.40; $p = 0.005$), and survival to hospital discharge with favorable neurologic status (13.9% vs. 5.1%; OR, 3.28; 95% CI, 1.17–9.20; $p = 0.02$), compared to the control group.

CASE 15-9, QUESTION 4: Because M.N. has an IV site and the time from cardiac arrest to ACLS was brief, epinephrine was chosen and a 1-mg bolus was given, followed with a 20-mL normal saline flush. The arm was elevated for 20 seconds to ensure adequate delivery. Thirty seconds after administration a 200-J shock is given (via biphasic manual defibrillator), but it fails to convert VF. What can be done now?

The most recently updated ACLS guideline calls for the use of amiodarone in cases of VF or pulseless VT that do not respond to CPR, shocks, and a vasopressor.[167]

IV AMIODARONE AND LIDOCAINE

The effect of amiodarone on VF or pulseless VT was studied in the ARREST (Amiodarone for Resuscitation of Refractory Sustained Ventricular

Tachyarrhythmias) trial.[171] This study was conducted in patients who experienced cardiac arrest in an out-of-hospital situation with therapy given by paramedics in the field. Patients who failed three stacked shocks and one dose of epinephrine with an electrical countershock were randomly assigned to amiodarone 300 mg IV bolus or placebo. This was followed by other antiarrhythmic agents historically used in ACLS (2,000 guidelines: lidocaine, procainamide, or bretylium) if the clinicians desired. Amiodarone significantly increased the chance of survival to hospital admission (44% vs. 34% of placebo group; $p = 0.03$), but survival to hospital discharge was not changed. Of note, 66% of patients received antiarrhythmic drug treatment for pulseless VT or VF after amiodarone administration.

The ALIVE (Amiodarone vs. Lidocaine in Ventricular Ectopy, $n = 347$) trial directly compared IV amiodarone 300 mg to lidocaine 1 to 1.5 mg/kg bolus.[173] In this trial, patients needed to fail three stacked shocks and epinephrine plus an additional shock to be eligible for randomization to either amiodarone or lidocaine. Amiodarone was given as an initial dose of 5 mg/kg followed by a shock. If unsuccessful, a dose of 2.5 mg/kg was given followed by a subsequent shock. Lidocaine was given as a 1.5 mg/kg bolus followed by a shock. If therapy failed, then a second bolus of 1.5 mg/kg was used with a subsequent shock. If the first antiarrhythmic drug failed, other routine antiarrhythmic drugs for cardiac arrest (per 2000 ACLS guidelines: e.g., procainamide, bretylium) could be tried. Patients given amiodarone were 90% more likely to experience the primary outcome, survival to hospital admission, than those given lidocaine ($p = 0.009$). Unfortunately, no significant advantage to hospital discharge occurred (5% vs. 3%).

On the basis of these findings, amiodarone is the only antiarrhythmic agent with proven ability to improve return of spontaneous circulation and short-term survival versus other antiarrhythmic therapy. However, it has not yet been shown to improve survival to hospital discharge.

M.N. is at serious risk of death as a result of VF. However, as long as M.N. remains in VF, it is appropriate to continue active therapy. If M.N. degenerates into asystole after this long period of VF, then the resuscitation efforts should be discontinued. However, if a patient only had a brief period of VF before having asystole, it is prudent to apply active therapy.

Pulseless Electrical Activity

CASE 15-10

QUESTION 1: J.D. is an 80-year-old woman who experiences cardiac arrest in the hospital. J.D. was in respiratory failure upon admission to the ED, where she underwent immediate intubation, had a peripheral IV placed, and upon transfer to the MICU, placed on assist/control mechanical ventilation with FiO_2 of 100%. A rhythm is noted on the monitor, but no femoral pulse is felt. M.N. is in PEA. How should J.D. be treated?

The clinical situation in which there is organized electrical activity on the monitor without a palpable pulse is called PEA. Although electrical activity is present, it fails to stimulate the contractile process. Virtually all patients in true PEA die. However, not all patients who present with a rhythm and no pulse are in true PEA. Therefore, it is important to rule out treatable causes in patients who appear to be in PEA. The major treatable causes are hypovolemia, hypoxia, acidosis, hyperkalemia, hypokalemia, hypothermia, cardiac tamponade, pulmonary embolism, acute coronary syndrome, trauma, and drug overdose. In the absence of an identifiable cause, the focus of resuscitation is to administer high-quality CPR, and after the initial rhythm check, resume CPR during the establishment of IV or IO (intraosseous) access.[167]

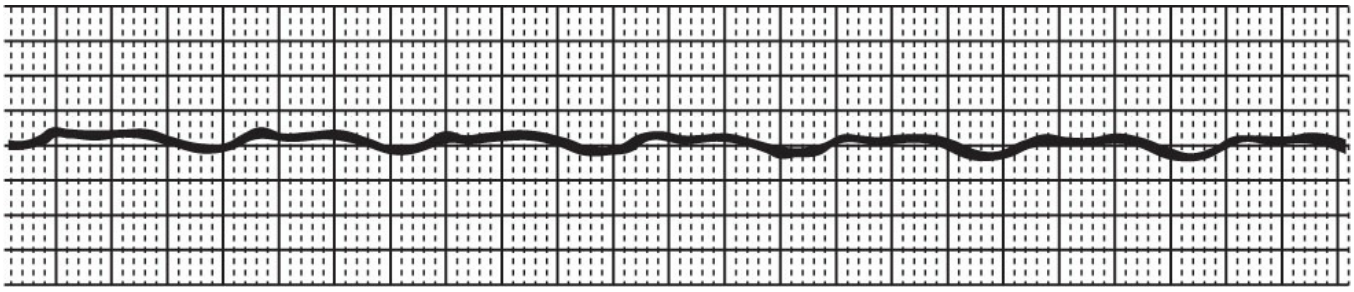


Figure 15-15 Asystole. There is no electrical activity detected in the heart resulting in a very low amplitude undulating waveform.

Once IV or IO access becomes available, administer epinephrine 1 mg every 3 to 5 minutes or give one dose of vasopressin 40 units in place of the first or second dose of epinephrine, as published studies have failed to demonstrate a survival advantage of either vasopressor for patients experiencing PEA.[167,169,170]

Asystole

CASE 15-11

QUESTION 1: K.K., a 73-year-old man, has a past medical history significant for hypertension and diverticulitis. Upon arrival at the OR for surgical correction of pericardial and pleural effusions, K.K. received etomidate, fentanyl, lidocaine, and succinylcholine. During placement of a double-lumen endotracheal tube, K.K. goes into cardiac arrest. The ECG shows a flat line, and the patient is determined to be in asystole (Fig. 15-15). Is this rhythm treatable?

Lack of electrical activity or asystole, like PEA, carries a grave prognosis. Its development usually indicates a prolonged arrest, which may explain its poor response to treatment. However, a few patients will go directly from a sinus rhythm into asystole and may be resuscitated. Enhanced parasympathetic tone, possibly attributable to a vagal reaction, manipulation of the airway from intubation, suctioning or insertion of an oral airway, or chest compression, may play a role in inhibiting supraventricular and ventricular pacemakers.[168]

A post hoc analysis performed by Wenzel et al.[168] demonstrated superior survival rates at the time of hospital admission in vasopressin-treated patients, compared with epinephrine-treated patients. However, no difference in intact neurologic survival was noted between the two treatment groups. Consequently, providers may choose to administer vasopressin 40 units IV (in place of the first or second dose of epinephrine) or epinephrine 1 mg IV every 3 to 5 minutes.

CASE 15-11, QUESTION 2: Does the timing of epinephrine dosing impact survival to hospital discharge in patients with non-shockable rhythms (asystole or PEA)?

A post hoc analysis of data from the Get With the Guidelines-Resuscitation study showed a stepwise reduction in survival to hospital discharge (primary study end point) with each 3-minute delay to epinephrine: (a) 1 to 3 minutes (OR 1.0, reference group); (b) 4 to 6 minutes (OR, 0.91; 95% CI, 0.82–1.00; $p = 0.055$); (c) 7 to 9 minutes (OR, 0.74; 95% CI, 0.63–0.88; $p < 0.001$); and (d) >9 minutes (OR, 0.63; 95% CI, 0.52–0.76; $p < 0.001$).[177]

CASE 15-11, QUESTION 3: What is the long-term prognosis for patients with non-shockable rhythms?

Goto et al.[175] assessed the impact of pre-hospital epinephrine administration on long-term outcomes seen in out-of-hospital cardiac arrest patients with non-shockable rhythms.[176] Epinephrine recipients showed superior 1-month survival rates compared to patients who did not receive pre-hospital epinephrine (3.9% vs. 2.2%; $p < 0.001$). However, pre-hospital administration of epinephrine did not result in improved 1-month favorable neurologic outcomes ($p = 0.62$).

Hypertensive Crises

Kristin Watson, Brian Watson, and Sandeep Devabhakthuni

CORE PRINCIPLES

CORE PRINCIPLES	CHAPTER CASES
① Hypertensive crisis is defined as a diastolic blood pressure greater than 120 mm Hg. This disorder can be further classified as hypertensive urgency or hypertensive emergency when there is evidence of acutely progressive end-organ damage.	**Case 16-1 (Question 1), Table 16-1**
② Risk factors for the development of a hypertensive crisis include, but are not limited to, medication nonadherence, cocaine use, and drug–drug and drug–food interactions.	**Case 16-1 (Question 1)**
③ Hypertensive urgency can be treated with oral antihypertensive agents including clonidine, labetalol, or captopril. Caution must be taken to prevent rapid reductions in blood pressure.	**Case 16-1 (Questions 2–6)** **Table 16-3**
④ The organs primarily affected as a result of a hypertensive emergency are the central nervous system, eyes, heart, and kidneys.	**Case 16-2 (Question 1)**
⑤ Parenteral therapy should be used to manage hypertensive emergencies, and therapeutic options are dictated by the affected organ(s) and comorbidities. Mean arterial pressure should be reduced by no more than 25% initially, then subsequently reduced toward a goal of 160/100 mm Hg, for most patients, during the next 2 to 6 hours. Gradually reduce blood pressure to normal, for most patients, during the next 8 to 24 hours.	**Case 16-2 (Questions 2, 3, 4, 5, 9, 10), Case 16-3 (Questions 1–6), Case 16-4 (Questions 1, 2), Table 16-4, Figure 16-1, Table 16-2**
⑥ Nitroprusside, a therapeutic option for hypertensive emergencies, has been associated with cyanide and thiocyanate toxicity, and monitoring is required to minimize the risk of these toxicities, especially in patients with renal impairment.	**Case 16-2 (Questions 6–8)**
⑦ The most commonly used agents for the management of postoperative hypertension are nicardipine, nitroglycerin, nitroprusside, and labetalol.	**Case 16-5 (Questions 1, 2, 3)**
⑧ Management of aortic dissection requires prompt control of blood pressure without increasing the force of cardiac contraction or heart rate.	**Case 16-6 (Question 1)**

The term hypertensive crisis is defined as a diastolic blood pressure (DBP) greater than 120 mm Hg.[1] These disorders are divided into two general categories: hypertensive emergency and hypertensive urgency (Table 16-1). If these disorders are not treated promptly, a high rate of morbidity and mortality will ensue.[2–5]

The term hypertensive emergency describes a clinical situation in which the elevated blood pressure (BP) is immediately life-threatening and needs to be lowered to a safe level (not necessarily to normal) within a matter of minutes to hours.[1,3] Hypertensive emergencies are associated with acutely progressive secondary organ damage (e.g., stroke or myocardial infarction [MI]). Hypertensive urgency is not an immediately life-threatening situation; a reduction in BP to a safe level can occur more slowly in the next 24 to 48 hours.[1,6]

Acute, potentially life-threatening elevations of BP can occur in previously normotensive individuals with acute glomerulonephritis, head injury, or severe burns; during pregnancy (eclampsia); and with the use of recreational drugs such as cocaine. Other causes include abrupt medication withdrawal or medication nonadherence, drug–drug interactions (including herbal medications), erythropoietin administration, or drug–food interactions (i.e., patients receiving monoamine oxidase inhibitors who ingest foods rich in tyramine).[7–9] In addition, poor systolic BP control has been identified as an independent risk factor for the development of hypertensive crisis.[10] Despite improvements in the recognition and treatment of hypertension, there has been an increase in the number of hospitalizations for hypertensive emergencies in the United States from 2000 to 2007 (101–111 cases per 100,000 hospitalizations). Fortunately, in-hospital mortality associated with these admissions decreased from 2.8% to 2.6% in this time period.[11]

Table 16-1

Hypertensive Emergency versus Urgency

	Emergency	Urgency
Blood pressure criteria	Diastolic >120 mm Hg[a]	Diastolic >120 mm Hg[a]
Life-threatening	Potentially	Not acutely
End-organ damage	Acute or progressing	Chronic; not progressing
Clinical manifestations	CNS (dizziness, N/V, encephalopathy, confusion, weakness, intracranial or subarachnoid hemorrhage, stroke) Eyes (ocular hemorrhage or funduscopic changes, blurred vision, loss of sight) Cardiac (left ventricular failure, pulmonary edema, MI, angina, aortic dissection) Renal failure or insufficiency	Optic disc edema

Treatment strategy	Immediate reduction in blood pressure; administer parenteral therapy (Table 16-2)	Reduction in blood pressure over several hours to days; administer oral therapy (Table 16-3)

[a] Degree of blood pressure elevation less diagnostic than rate of pressure rise and presence of concurrent diseases or end-organ damage. See Chapter 9, Essential Hypertension, for staging of hypertension.
CNS, central nervous system; MI, myocardial infarction; N/V, nausea and vomiting.

CLINICAL PRESENTATION OF HYPERTENSIVE URGENCY

There are limited data describing the presentation and characteristics of those patients with a hypertensive urgency. Symptoms may include headache, dizziness, visual changes, chest discomfort, nausea, epistaxis, fatigue, and psychomotor agitation.[12] It should be noted that not all patients presenting with a hypertensive urgency will have symptoms.

CLINICAL PRESENTATION OF HYPERTENSIVE EMERGENCY

Similar to hypertensive urgencies, hypertensive emergencies typically occur in those with a history of hypertension. This suggests that hypertensive emergencies are almost entirely preventable.[13,14] Hypertensive emergencies tend to occur in patients with catecholamine-producing adrenal tumors (pheochromocytoma) or renal vascular disease. Additionally, hypertensive emergencies occur more often in African Americans than in Caucasians, among patients who have no primary care physician, and those who do not adhere to treatment regimens.[13,15]

Symptoms associated with hypertensive emergency are highly variable and reflect the degree of damage to specific organ systems. Rapid, severe BP elevation is not always the hallmark of a hypertensive emergency. The primary sites of damage are the central nervous system, heart, kidneys, and eyes. Although hypertensive emergencies are much less common than hypertensive urgencies, it is often difficult to know whether end-organ dysfunction is new or has progressed without a thorough patient history.

Central Nervous System

Central nervous system abnormalities are the most commonly reported complications in hypertensive emergencies. Symptoms may include a severe headache with or without dizziness, nausea, vomiting, and anorexia. Mental confusion with apprehension indicates more severe damage, as does nystagmus, localized weakness, or a positive Babinski sign (i.e., upward extension of the great toe and spreading of the smaller toes when moderate pressure is applied along a curve from the sole to the ball of the foot). Central nervous system damage may rapidly progress, resulting in coma or death. If a cerebrovascular accident has occurred, slurred speech or motor paralysis may be present.[13]

Other Complications

Cardiac consequences are the second most common complication of hypertensive emergency reported. Presentations may include heart failure (HF), acute pulmonary edema, and/or an acute coronary syndrome. Ocular symptoms of hypertensive emergency usually are related to changes in visual acuity. Complaints of blurred vision or loss of eyesight are often associated with funduscopic findings of hemorrhages, exudates (yellow deposits within the retina as a result of leaks from capillaries and microaneurysms), and occasionally papilledema (edema of the optic nerve). Acute kidney injury can also develop. Markers of renal dysfunction include hematuria, proteinuria, and elevated serum blood urea nitrogen and serum creatinine levels.

OVERVIEW OF TREATMENT

Oral versus Parenteral Therapy

Hypertensive urgency is not an indication for parenteral treatment; oral antihypertensive regimens are more appropriate. Practitioners should exercise caution in the treatment of patients with elevated BP in the absence of target organ damage. Aggressive dosing to rapidly lower BP is not without risk and can lead to hypotension and subsequent morbidity. Some have suggested that the term hypertensive urgency leads to overly aggressive treatment and should be discarded in favor of a less ominous term such as uncontrolled BP.[6] In contrast, hypertensive emergencies require immediate hospitalization, generally in an intensive care unit, and the administration of parenteral antihypertensive medications to reduce arterial pressure.[16] Effective therapy greatly improves the prognosis, reverses symptoms, and arrests the progression of end-organ damage.[17–19] Whether treatment can completely reverse end-organ damage is related to two factors: how soon treatment is initiated and the extent of damage at the initiation of therapy.

There are two fundamental concepts in the management of hypertensive emergencies. First, immediate and intensive therapy is required and takes precedence over time-consuming diagnostic procedures. Second, the choice of drugs will depend on how their time course of action and hemodynamic and metabolic effects meet the needs of the emergent situation. If encephalopathy, acute left ventricular failure, dissecting aortic aneurysm, eclampsia, or other end-organ damage is present, the BP should be lowered promptly with rapid-acting, parenteral antihypertensive medications such as clevidipine, esmolol, enalaprilat, fenoldopam, hydralazine, labetalol, nicardipine, nitroglycerin, or nitroprusside (Table 16-2).[1,3,4,20–24] If a slower BP reduction over the course of several hours or days is acceptable, as in the case of a hypertensive urgency, rapid-acting oral therapy using captopril, clonidine, labetalol, or minoxidil may be used (Table 16-3).[3,4,24–26] Figure 16-1 provides an overview of the management of a hypertensive crisis. A summary of treatment recommendations for acutely lowering BP for selected indications is listed in Table 16-4.

Table 16-2

Parenteral Medications Commonly Used in the Treatment of Hypertensive Emergencies

Medication (Brand Name)/Class	Dose/Route	Onset of Action	Duration of Action
Clevidipine (Cleviprex)/calcium-channel blocker	Initial: 1–2 mg/hour; titrate dose to desired BP or to a max of 16 mg/hour	2–4 minutes	10–15 minutes after D/C infusion
Enalaprilat[a] (Vasotec IV)/ACE inhibitor	0.625–1.25 mg IV every 6 hours	15 minutes (max, 1–4 hours)	6–12 hours
Esmolol[b] (Brevibloc)/β-adrenergic blocker	250–500 mcg/kg for 1 minute, then 50–300 mcg/kg/minute	1–2 minutes	10–20 minutes
Fenoldopam (Corlopam)/dopamine-1 agonist	0.1–0.3 mcg/kg/minute	<5 minutes	30 minutes
Hydralazine[c] (generic) (20 mg/mL)/arterial vasodilator	10–20 mg IV	5–20 minutes	2–6 hours
Labetalol[d] (Normodyne)/α- and β-adrenergic blocker	2 mg/minute IV or 20–80 mg every 10 minutes up to 300 mg total dose	2–5 minutes	3–6 hours

Nicardipine[e] (Cardene IV)/calcium-channel blocker	Initiate at 5 mg/hour IV increased by 2.5 mg/hour every 5 minutes to desired BP or a max of 15 mg/hour every 15 minutes, may decrease to 3 mg/hour after response achieved	2–10 minutes (max, 8–12 hours)	40–60 minutes after D/C infusion
Nitroglycerin[f] (Tridil, Nitro-Bid IV, Nitro-Stat IV)/arterial and venous vasodilator	IV infusion 5–100 mcg/minute	2–5 minutes	5–10 minutes after D/C infusion
Nitroprusside[g] (Nipride, Nitropress)/arterial and venous vasodilator	IV infusion.[a] Start: 0.5 mcg/kg/minute Usual: 2–5 mcg/kg/minute Max: 8 mcg/kg/minute	Seconds	3–5 minutes after D/C infusion

Medication	**Major Side Effects (All Can Cause Hypotension)**	**Avoid or Use Cautiously in Patients With These Conditions**
Clevidipine	Atrial fibrillation, nausea, vomiting, headache, acute renal failure, reflex tachycardia, MI	Allergy to soybeans, soy products, eggs or egg products, severe aortic stenosis, defective lipid metabolism, HF
Enalaprilat	Hyperkalemia, acute kidney injury in those who are volume depleted	Hyperkalemia, bilateral renal artery stenosis, pregnancy (teratogenic)
Esmolol	Nausea, thrombophlebitis, painful extravasation	Asthma, bradycardia, decompensated HF, advanced heart block
Fenoldopam	Tachycardia, headache, nausea, flushing	Glaucoma
Hydralazine	Tachycardia, headache, angina	Angina pectoris, MI, aortic dissection
Labetalol	Abdominal pain, nausea, vomiting, diarrhea	Asthma, bradycardia, decompensated HF
Nicardipine	Headache, flushing, nausea, vomiting, dizziness, tachycardia; local thrombophlebitis change infusion site after 12 hours	Angina pectoris, decompensated HF, increased intracranial pressure
Nitroglycerin	Methemoglobinemia, headache, tachycardia, nausea, vomiting, flushing, tolerance with prolonged use	Pericardial tamponade, constrictive pericarditis, or increased intracranial pressure
Nitroprusside	Nausea, vomiting, diaphoresis, weakness, thiocyanate toxicity,[h] cyanide toxicity (rare)[i] Chest pain, nausea, vomiting, dizziness, headache, nasal congestion, arrhythmia	Renal failure (thiocyanate accumulation), hepatic impairment (cyanide toxicity), pregnancy, increased intracranial pressure, acute coronary syndrome

[a] Not approved by the U.S. Food and Drug Administration for treatment of acute hypertension.

[b] Approved for intraoperative and postoperative treatment of hypertension.

[c] Parenteral hydralazine is an intermediate treatment between oral agents and more aggressive therapies such as nitroprusside. It can be given IV or intramuscularly, but there is no appreciable difference in onset of action (20–40 minutes) between the two routes. This slow onset minimizes hypotension.

[d] Labetalol is contraindicated in acute decompensated heart failure because of its β-blocking properties. Infusions start at 2 mg/minute and are titrated until a satisfactory response or a cumulative dose of 300 mg is achieved.

[e] Indicated for short-term treatment of hypertension when the oral route is not feasible or desirable.

[f] Requires special delivery system owing to drug binding to polyvinyl chloride tubing. Also see Chapters 12, Chronic Stable Angina, and Chapter 13, Acute Coronary Syndromes, for further information regarding nitroglycerin.

[g] The container should be wrapped with metal foil to prevent light-induced decompensation once reconstituted; the product will be a red-brown solution. Under these conditions, the solution is stable for 4 to 24 hours. A rising BP may indicate loss of potency. A change in color to yellow does not indicate effectiveness. The appearance of a dark brown, green, or blue color indicates loss in activity. When changing to a new bag, the administration rate may require adjustment.

[h] Thiocyanate levels rise gradually in proportion to the dose and duration of administration. The half-life of thiocyanate is 2.7 days with normal renal function and 9 days in patients with renal failure. Toxicity occurs after 7 to 14 days in patients with normal renal function and after 3 to 6 days in renal failure patients. Thiocyanate serum levels should be measured after 3 to 4 days of therapy, and the drug should be discontinued if levels exceed 10 to 12 mg/dL. Thiocyanate toxicity causes a neurotoxic syndrome of toxic psychosis, hyperreflexia, confusion, weakness, tinnitus, seizures, and coma.

[i] Signs of cyanide toxicity include lactic acidosis, hypoxemia, tachycardia, altered consciousness, seizures, and the smell of almonds on the breath. Concurrent administration of sodium thiosulfate or hydroxocobalamin may reduce the risk of cyanide toxicity in high-risk patients.

ACE, angiotensin-converting enzyme; BP, blood pressure; D/C, discontinued; HF, heart failure; IV, intravenous; MI, myocardial infarction.

Table 16-3

Oral Medications Commonly Used in the Treatment of Hypertensive Urgencies

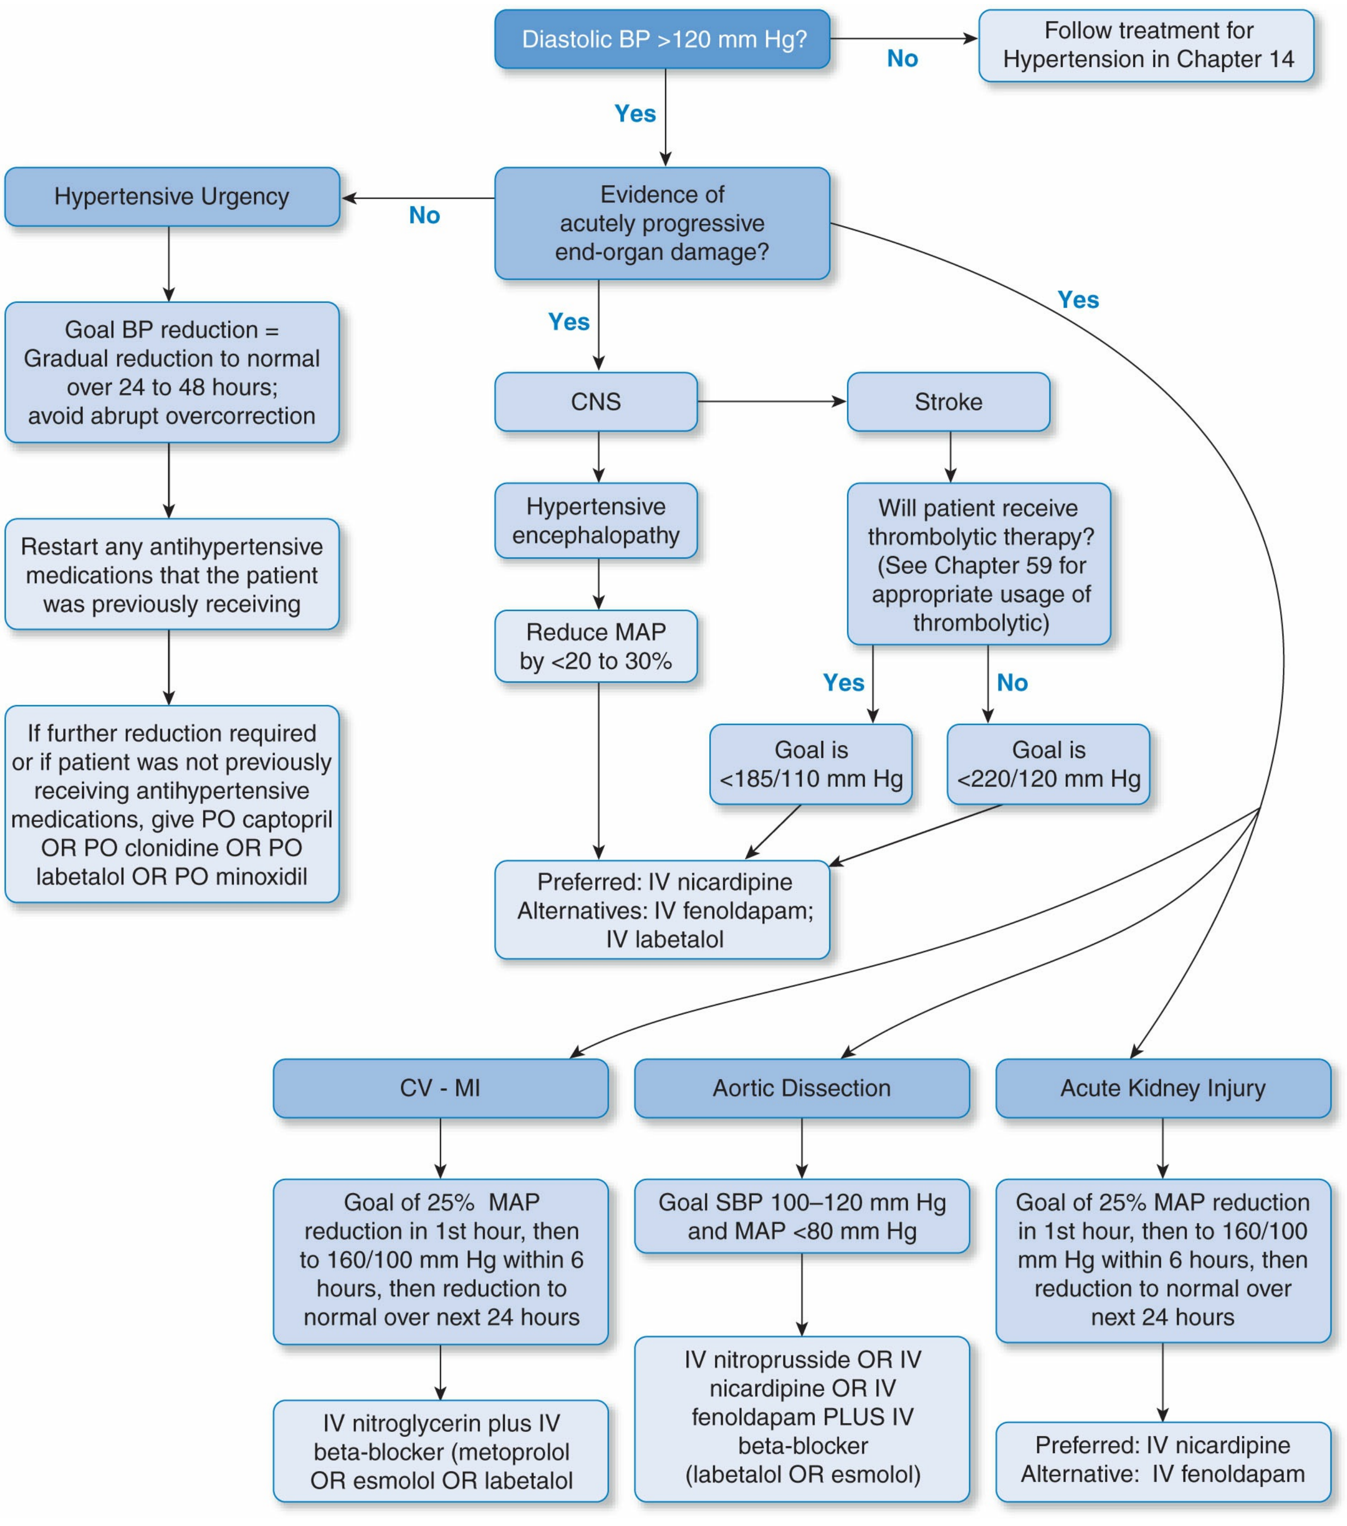
Medication[a] (Brand Name)	**Dose/Route**	**Onset of Action**	**Duration of Action**	**Major Side Effects[a]**	**Avoid or Use Cautiously in Patients With These Conditions**
Captopril[b] (Capoten) 12.5-, 25-, 50-, 100-mg tablets ACE inhibitor	6.5–50 mg PO	15 minutes	4–6 hours	Hyperkalemia, angioedema, increased SCr if volume depletion, rash, pruritus, loss of taste	Renal artery stenosis, hyperkalemia, volume depletion, acute kidney injury, pregnancy
Clonidine (Catapres) 0.1-, 0.2-, 0.3-mg tablets Central α_2-agonist	0.1–0.2 mg PO initially, then 0.1 mg/hour up to 0.8 mg total	0.5–2 hours	6–8 hours	Sedation, dry mouth, bradycardia, constipation	Altered mental status, severe carotid artery stenosis
Labetalol (Normodyne, Trandate) 100-, 200-, 300-mg tablets α- and β-adrenergic blocker	200–400 mg PO repeated every 2–3 hours	30 minutes–2 hours	4 hours	Orthostatic hypotension, nausea, vomiting	HF, asthma, bradycardia
Minoxidil (Loniten) 2.5-, 10-mg tablets Arterial and	5–20 mg PO	30–60 minutes; maximum response in 2–4 hours	12–16 hours	Tachycardia, fluid retention	Angina, HF

venous vasodilator					

[a] All may cause hypotension, dizziness, and flushing.

[b] Other oral ACE inhibitors too slow in onset to be useful but should be used for maintenance therapy to improve adherence as captopril requires multiple daily doses.

ACE, angiotensin-converting enzyme; HF, heart failure, PO, orally; SCr, serum creatinine.



Diastolic BP >120 mm Hg?
No
Follow treatment for Hypertension in Chapter 14
Yes
Evidence of acutely progressive end-organ damage?
No
Hypertensive Urgency
Goal BP reduction = Gradual reduction to normal over 24 to 48 hours; avoid abrupt overcorrection
Restart any antihypertensive medications that the patient was previously receiving
If further reduction required or if patient was not previously receiving antihypertensive medications, give PO captopril OR PO clonidine OR PO labetalol OR PO minoxidil
Yes
CNS
Stroke
Hypertensive encephalopathy
Reduce MAP by <20 to 30%
Will patient receive thrombolytic therapy? (See Chapter 59 for appropriate usage of thrombolytic)
Yes
No
Goal is <185/110 mm Hg
Goal is <220/120 mm Hg
Preferred: IV nicardipine Alternatives: IV fenoldapam; IV labetalol
Yes
CV - MI
Goal of 25% MAP reduction in 1st hour, then to 160/100 mm Hg within 6 hours, then reduction to normal over next 24 hours
IV nitroglycerin plus IV beta-blocker (metoprolol OR esmolol OR labetalol
Aortic Dissection
Goal SBP 100–120 mm Hg and MAP <80 mm Hg
IV nitroprusside OR IV nicardipine OR IV fenoldapam PLUS IV beta-blocker (labetalol OR esmolol)
Acute Kidney Injury
Goal of 25% MAP reduction in 1st hour, then to 160/100 mm Hg within 6 hours, then reduction to normal over next 24 hours
Preferred: IV nicardipine Alternative: IV fenoldapam

Figure 16-1 Overview of management for a hypertensive crisis. BP, blood pressure; CNS, central nervous system; IV, intravenous; MAP, mean arterial pressure; MI, myocardial infarction; SBP, systolic blood pressure.

Goals of Therapy

The rate of BP lowering must be individualized depending on whether the patient presents with a hypertensive urgency or emergency. Also, ischemic damage to the heart and brain can be provoked by a precipitous fall in BP.[26–30] As treatment is initiated, clinicians should recognize that the elderly and patients with severely defective autoregulatory mechanisms are at high risk for developing hypotensive complications. The latter group includes those with autonomic dysfunction or fixed sclerotic stenosis of cerebral or neck arteries.[31] In addition, patients who have chronically elevated BP are less likely to tolerate abrupt reductions in their BP, and the amount of reduction appropriate for those patients is somewhat less than for those whose BP is acutely elevated.

For hypertensive emergencies, it is recommended that the mean arterial pressure be reduced initially by no more than 25% (within minutes to 1 hour); then if stable, this should be followed by further reduction toward a goal of 160/100 mm Hg within 2 to 6 hours and gradual reduction to normal during the next 8 to 24 hours.[4] A DBP of 100 to 110 mm Hg is an appropriate initial therapeutic goal.[1] Lower pressures are typically indicated for patients with aortic dissection (Case 16-6).

Another exception to this rule applies in patients with acute cerebrovascular accidents. Cerebral autoregulation is disrupted in this setting, and the use of antihypertensives may cause a reduction in cerebral blood flow and increasing morbidity.[32] Current guidelines recommend lowering BP after acute ischemic stroke if the systolic BP is greater than 220 mm Hg or the DBP is greater than 120 mm Hg in patients ineligible for thrombolytic therapy; a lower blood goal can be achieved, if medically necessary, to manage a condition such as a MI or aortic dissection. The systolic BP should be lowered to less than 185 mm Hg and DBP to less than 110 mm Hg in candidates for thrombolytics.[33] The systolic BP should be maintained at less than 180 mmHg and the DBP at less than 105 mmHg for the first 24 hours after thrombolytic therapy. A lower BP in patients undergoing thrombolytic therapy reduces the risk of intracerebral bleeding.[33] Additionally, in those with hypertensive encephalopathy, cerebral hypoperfusion may occur if the mean BP is reduced by more than 40%.[34] Thus, in the presence of hypertensive encephalopathy it is suggested that within the first hour of treatment the mean pressure be lowered by no more than 20% or to a DBP of 100 mm Hg, whichever is greater.[34,35]

Table 16-4

Treatment Recommendations for Hypertensive Emergency

Clinical Presentation	Recommendation	Rationale
Aortic dissection	Nitroprusside, nicardipine, or fenoldopam plus esmolol or IV metoprolol; labetalol; trimethaphan. Avoid inotropic therapy.	Vasodilator will decrease pulsatile stress in aortic vessel to prevent further dissection expansion. β-blockers will prevent vasodilator-induced reflex tachycardia.
Angina, myocardial infarction	Nitroglycerin plus esmolol or metoprolol; labetalol. Avoid nitroprusside.	Coronary vasodilation, decreased cardiac output, myocardial workload, and oxygen demand. Nitroprusside may cause coronary steal.
Acute pulmonary edema, left ventricular failure	Nitroprusside, or nitroglycerin and a loop diuretic. Alternative: enalaprilat. Avoid nondihydropyridines, β-blockers.	Promotion of diuresis with venous dilatation to decrease preload. Nitroprusside, enalaprilat decrease afterload. Nicardipine may increase stroke volume.
Acute kidney injury	Nicardipine or fenoldopam. Avoid nitroprusside, enalaprilat.	Peripheral vasodilation without affecting renal clearance.
Cocaine overdose	Nicardipine, fenoldopam, verapamil, or nitroglycerin. Alternative: labetalol. Avoid β-selective blockers.	Vasodilation effects without potential unopposed α-adrenergic receptor stimulation. CCBs control overdose-induced vasospasm.
Pheochromocytoma	Nicardipine, fenoldopam, or verapamil. Alternatives: labetalol. Avoid β-selective blockers.	Vasodilation effects without potential unopposed α-adrenergic receptor stimulation.
Hypertensive encephalopathy, intracranial hemorrhage, subarachnoid hemorrhage, ischemic stroke, thrombotic stroke	Nicardipine, clevidipine or labetalol. Avoid nitroprusside, nitroglycerin, enalaprilat, hydralazine.	Vasodilation effects without compromised CBF induced by nitroprusside and nitroglycerin. Enalaprilat and hydralazine may lead to unpredictable BP changes when carefully controlled BP management is required.

BP, blood pressure; CBF, cerebral blood flow; CCB, calcium-channel blocker; IV, intravenous.

HYPERTENSIVE URGENCIES

Patient Assessment

CASE 16-1

QUESTION 1: M.M. is a 60-year-old African American man with a long history of HF with a preserved ejection fraction (HFpEF), poorly controlled hypertension believed to be caused by nonadherence, and a history of MI. He was referred from a community health center this morning for a thorough evaluation of his elevated BP. He has not taken his enalapril, carvedilol, or amlodipine for the past 7 days. M.M. is completely asymptomatic. Physical examination reveals a BP of 180/120 mm Hg and a pulse of 92 beats/minute. Funduscopic examination is pertinent for mild arteriolar narrowing, without hemorrhages or exudates. The discs are flat. His lungs are clear, and the cardiac examination is unremarkable. The electrocardiogram indicates normal sinus rhythm at a rate of 90 beats/minute. The chest radiograph is interpreted as mild cardiomegaly. Serum electrolytes, blood urea nitrogen, and serum creatinine are within normal limits. A urinalysis is significant for 2+ proteinuria. How quickly should his BP be lowered, and what therapeutic options are available?

The absolute magnitude of BP elevation does not in itself constitute a medical emergency requiring an acute reduction in BP. There is no evidence of encephalopathy, cardiac decompensation, chest pain, or rapid change in renal function. Therefore, no evidence exists to indicate a rapid deterioration in the function of target organs. One would classify M.M.'s case as a hypertensive urgency.

As is often the case, M.M.'s lack of BP control is related to medication nonadherence. M.M.'s clinical presentation requires that his BP be lowered during the next 12 to 24 to 48 hours while being careful not to induce hypotension. Rapid-acting oral agents can be used for this purpose; parenteral therapy is not warranted. A number of different oral regimens using clonidine, captopril, labetalol, or minoxidil are available. Restarting his medications in a controlled manner so as not to drop his BP too rapidly may also be a reasonable option for treatment. Later, he can be converted to a regimen designed to enhance adherence by selecting medications with once-daily dosing. For example, lisinopril or another long-acting angiotensin-converting enzyme (ACE) inhibitor would be preferred for maintenance instead of the enalapril previously prescribed. One should also determine and address barriers to

---

medication adherence with the patient including cost of therapy, lack of understanding of the benefits of therapy, misconceptions of the side effect profiles, and so forth. Timely follow-up within 1 week after treatment of hypertensive urgency is of paramount importance for the appropriate management of these patients.

Oral Drug Therapy

RAPIDLY ACTING CALCIUM-CHANNEL BLOCKERS

CASE 16-1, QUESTION 2: M.M.'s physician has ordered immediate-release nifedipine to be given 10 mg sublingually. Is this appropriate therapy to treat his hypertensive urgency?

Captopril, clonidine, labetalol, and minoxidil have all been used to lower BP acutely. These oral agents take several hours to adequately lower pressure and are therefore useful in treating hypertensive urgencies but not emergencies. Oral acting ACE inhibitors, other than captopril, are not useful for acutely lowering BP because of a slower onset of action.

The immediate-release calcium-channel blockers, including diltiazem, verapamil, and nicardipine, can rapidly lower BP; however, the most extensive experience is with nifedipine. Nifedipine, when given orally or by the "bite and swallow" method, was previously recommended as a rapid-acting alternative to parenteral therapy in the acute management of hypertension. However, its use has been associated with life-threatening adverse events related to ischemia, MI, and stroke.[26–30] The cavalier use of immediate-release nifedipine to acutely lower BP is potentially dangerous and should be discouraged.[36,37] M.M.'s BP can be managed safely using other oral medications. Captopril, clonidine, or labetalol can be used to lower his BP, and he can be restarted on his oral maintenance regimen with appropriate follow-up care.

CLONIDINE

CASE 16-1, QUESTION 3: A decision is made not to use nifedipine, but rather to give M.M. oral clonidine. What is an appropriate starting and maintenance dose?

Clonidine is considered a safe, effective first-line therapy for hypertensive urgency. It is a centrally acting, α_2-adrenergic agonist that inhibits sympathetic outflow from the central nervous system. BP can be lowered gradually over the course of several hours using oral clonidine. Traditional dosing regimens have included an initial oral loading dose (0.1–0.2 mg) followed by repeated doses of 0.1 mg/hour until the desired response is achieved or until a cumulative dose of 0.8 mg is reached.[38] Some authors, however, have cautioned against the use of sequential loading doses, citing lack of benefit over placebo and the potential for unpredictable adverse effects, particularly abrupt occurrences of hypotension.[39] If loading doses are to be used, it is especially important to reduce doses in patients with volume depletion, those who have recently used other antihypertensive drugs, and the elderly.[1,23,40]

The acute response to oral clonidine loading is not predictive of the daily dose required to maintain BP control. Maintenance oral therapy with clonidine is somewhat empiric; however, total daily doses should be spread between 2 and 3 times daily dosing owing to the drug's short half-life.

Adverse Effects and Precautions

CASE 16-1, QUESTION 4: What are the adverse effects and precautions that should be considered before recommending the use of clonidine?

Oral clonidine is generally well tolerated. Adverse effects include orthostatic hypotension, bradycardia, sedation, dry mouth, and dizziness. Clonidine can decrease cerebral blood flow by up to 28%; it should not be used in patients with severe cerebrovascular disease.[41] Clonidine also should be avoided in patients with HF, bradycardia, sick sinus syndrome, or cardiac conduction defects,[23] as well as in patients at risk of medication nonadherence because of the rebound hypertension.[42,43]

OTHER ORAL DRUGS

Captopril

CASE 16-1, QUESTION 5: M.M. has a history of HFpEF and normal renal function. Based on these findings, would captopril be a reasonable choice for initial treatment? How should it be given? What if his blood urea nitrogen or serum creatinine were elevated?

Captopril has been used both orally and sublingually to acutely lower BP.[44,45] Captopril decreases both afterload and preload, and lowers total peripheral vascular resistance.[23] For this reason, captopril and other ACE inhibitors are often considered the drugs of choice in patients with HF with reduced ejection fraction as they have been shown to reduce mortality in this patient population (see Chapter 14, Heart Failure, for further discussion). M.M has HFpEF; the evidence of using ACE inhibitors in improving cardiovascular outcomes in this patient population is not strong. However, given that M.M. appeared to be well controlled on his enalapril therapy before abruptly stopping his medications, it is reasonable to restart a rapid ACE inhibitor and reinforce medication adherence issues.

After oral administration, the onset of action of captopril occurs within minutes and peaks 30 to 90 minutes later.[46] Clinically, it reduces BP within 10 to 15 minutes, with effects persisting for 2 to 6 hours. Sublingual captopril is as effective as nifedipine but without reflex tachycardia in acutely reducing mean arterial pressure in both urgent and emergent conditions.[45–48]

Despite these beneficial effects, captopril, as well as long-acting ACE inhibitors, must be used with caution in patients with renal insufficiency or volume depletion. In most cases, an elevated blood urea nitrogen or serum creatinine will provide a clue to the existence of these conditions; however, captopril can also induce renal failure in patients with bilateral renal artery stenosis or renal artery stenosis in a solitary kidney. Such conditions may not be easy to detect in the context of an acute hypertensive emergency. Therefore, in patients in whom these conditions can be excluded, captopril can be considered for therapy. First-dose hypotension is a common limiting factor with captopril use. This complication is most likely to occur in the elderly and in patients with high renin levels such as those who are volume depleted or those receiving diuretics. Under these circumstances, initial doses should not exceed 12.5 mg, with repeat doses an hour or more later if necessary. Therefore, captopril would be a reasonable choice as initial therapy in M.M., which can later be replaced by a longer-acting ACE inhibitor.

Minoxidil and Labetalol

CASE 16-1, QUESTION 6: What other oral agents are used in the treatment of hypertensive urgency?

Minoxidil, a potent oral vasodilator, has been used successfully in the treatment of hypertensive urgencies.[49,50] An oral loading dose of 10 to 20 mg produces a maximal BP response in 2 to 4 hours and can be followed by a dose of 5 to 20 mg every 4 hours if necessary. Unfortunately, its onset of action is slower than that of clonidine or captopril. Another complicating factor is that

---

β-blockers and loop diuretics generally must be used concomitantly to counteract minoxidil-induced reflex tachycardia and fluid retention.[50] Because of this, minoxidil should only be prescribed by those who have experience with prescribing this agent and managing these adverse effects. These adverse effects make this agent a less than ideal choice in M.M. because of his history of HF. Minoxidil should be used only in patients presenting with hypertensive urgency who are not responding to other antihypertensive therapies or who have previously been taking this agent.

Oral labetalol, a combined α- and β-receptor antagonist, is an alternative to oral clonidine or captopril for the treatment of severe hypertension, but the most appropriate dosing regimen remains to be determined.[51–54] Initial doses of 100 to 300 mg may provide a sustained response for up to 4 hours.[52] Labetalol (200 mg given at hourly intervals to a maximum dose of 1,200 mg) was comparable to oral clonidine in reducing mean arterial pressure.[54] An alternative regimen using 300 mg initially followed by 100 mg at 2-hour intervals to a maximum of 500 mg was also successful in acutely lowering BP.[53] Other literature has reported that a single loading dose of 200 to 400 mg does not appear to be effective in achieving an adequate BP response.[55] Because labetalol can cause profound orthostatic hypotension, patients should remain in the supine position and should be checked for orthostasis before ambulation. In addition, labetalol should be avoided in patients with asthma, bradycardia, or advanced heart block.

HYPERTENSIVE EMERGENCIES

Patient Assessment

CASE 16-2

QUESTION 1: M.R., a 55-year-old African American man, presents to the emergency department with a 3-day history of progressively increasing shortness of breath. During the past 2 days, he experienced a severe headache unrelieved by ibuprofen, as well as substernal chest pain, anorexia, and nausea. His medical history includes asthma and chronic stable angina. His medications include albuterol via metered-dose inhaler, furosemide, isosorbide dinitrate, felodipine, and lisinopril; however, he discontinued these medications on his own 3 weeks ago.

Physical examination reveals an anxious-appearing man who is alert, oriented, and in moderate respiratory distress. His vital signs include a heart rate of 125 beats/minute, respiratory rate of 36 breaths/minute, BP of 220/145 mm Hg without orthostasis, and a normal body temperature. Funduscopic examination shows arteriolar narrowing and arteriovenous nicking without hemorrhages, exudates, or papilledema. No jugular venous distention is observed, but bilateral carotid bruits are present. Chest examination reveals decreased breath sounds with bilateral rales extending to the tip of the scapula. M.R.'s heart is displaced 2 cm to the left of the midclavicular line with no thrills or heaves. The rhythm is regular with an S_3 and an S_4 gallop; no murmurs are noted. The remainder of M.R.'s examination is within normal limits.

Significant laboratory values include the following:

Sodium, 142 mEq/L
Potassium, 4.9 mEq/L
Chloride, 101 mEq/L
Bicarbonate, 23 mEq/L
Urea nitrogen, 30 mg/dL
Serum creatinine, 1.2 mg/dL
Hematocrit, 38%
Hemoglobin, 13 g/dL
White blood cell count and differential, within normal limits
Troponin—negative × 2

Urinalysis shows 1+ hemoglobin and 1+ protein. Microscopic examination of the urine reveals 5 to 10 red blood cells per high-power field and no casts. Pulse oximetry reveals an oxygen saturation of 88%. An electrocardiogram demonstrates sinus tachycardia and left ventricular hypertrophy. The chest radiograph shows moderate cardiomegaly and bilateral fluffy infiltrates.

What aspects of M.R.'s history and physical examination are characteristic of an emergent need to immediately lower his BP?

Hypertensive crisis occurs most often in African American men and in individuals between the ages of 40 and 60. Furthermore, many patients who present with hypertensive crisis have a recent history of discontinuing the use of their antihypertensives,[13,15] as is the case with M.R. in Case 16-2 and M.M. in Case 16-1.

Recent-onset severe headache, nausea, and vomiting are consistent with central nervous system signs of severe hypertension, as are the acute onset of angina (substernal pain) and acute HF (shortness of breath, increased pulse and respiratory rate, cardiomegaly, S_3, and chest radiographic findings of pulmonary edema). The absence of signs of right-sided HF such as jugular venous distention or hepatomegaly suggests an acute onset of HF caused by hypertension as opposed to a gradual worsening of chronic HF. M.R.'s urinary sediment is relatively unimpressive at this time, especially in light of his history, and his ocular complications are minimal. M.R.'s presentation is considered hypertensive emergency because of the presence of HF symptoms; M.R. should be admitted to the hospital as intravenous (IV) antihypertensive therapy is warranted.

Parenteral Drug Therapy

NITROPRUSSIDE

CASE 16-2, QUESTION 2: M.R. is to be started on nitroprusside. Is this an appropriate choice of drug? What alternatives to nitroprusside are available?

M.R.'s arterial pressure should be lowered with parenteral medications, which have a rapid onset of action. Nitroprusside, fenoldopam, and IV nitroglycerin all decrease total peripheral resistance rapidly with minimal effect on myocardial oxygen consumption and heart rate. Of these agents, either nitroprusside or fenoldopam would be preferred in patients with hypertension accompanied by decompensated HF in the absence of MI. Parenteral nitroglycerin is similar to nitroprusside except that it has a relatively greater effect on the venous circulation and less effect on arterioles. It is most useful in patients presenting with angina secondary to coronary insufficiency, ischemic heart disease, MI, or hypertension after coronary bypass surgery (also see Case 16-3, Question 6). In addition, nitroprusside and IV nitroglycerin may both decrease elevated left ventricular diastolic pressures in patients presenting with hypertensive emergency. Although nitroglycerin would be helpful for someone who is experiencing chest pain in the setting of an MI, this patient is not having an acute coronary syndrome, which is confirmed by negative troponins and electrocardiogram. Before considering nitroprusside, it is important to consider the etiology of the chest pain. As described above, the chest pain is likely due to acute-onset HF due to severe hypertension. Based on the signs and symptoms, it is not likely to have been caused by ischemic heart disease. In the setting of coronary ischemia, nitroglycerin has been shown to be more beneficial than nitroprusside; however, this patient does not have evidence of active coronary ischemia. Because the clinical presentation is more consistent with acute-onset HF, it

---

is important to focus on reducing peripheral resistance and decreasing elevated left ventricular diastolic pressures. Nitroprusside provides an advantage here because it provides both arterial and venous vasodilation, allowing for further reduction in peripheral resistance and left ventricular diastolic pressures. Nitroglycerin has a relatively greater effect on venous circulation, especially at lower doses. Thus, nitroprusside would be preferred in this patient.

Fenoldopam and nitroprusside are equally efficacious in acutely lowering BP.[56–59] Both medications have an immediate onset, are easily titratable, have a short duration of action, and are relatively well tolerated.[60–63] Unlike nitroprusside, fenoldopam does not cause cyanide or thiocyanate toxicity. However, fenoldopam is associated with dose-related tachycardia and should be avoided in those with active coronary ischemia.

Therefore, in the absence of any significant renal or liver disease, nitroprusside is the preferred treatment for M.R.

Hemodynamic Effects

Nitroprusside has many pharmacologic effects that should improve M.R.'s condition. It dilates both venous and arterial vessels, thereby increasing venous capacitance and decreasing the venous return or preload on the heart (see Chapter 14, Heart Failure). A decrease in the pulmonary capillary wedge pressure and ventricular filling pressure will ultimately improve M.R.'s pulmonary edema. Afterload is also decreased as a result of arterial dilation. This action increases cardiac output, reduces arterial pressure, and increases tissue perfusion.

Concurrent Use of Diuretics

CASE 16-2, QUESTION 3: Should M.R. be given a diuretic before nitroprusside therapy is begun?

Administration of potent IV diuretics is relatively ineffective in the acute treatment of hypertensive crisis except in patients with concomitant volume overload or HF. Many patients with hypertensive emergencies are vasoconstricted and have normal or reduced plasma volumes; therefore, diuretics have little effect and may actually aggravate renal impairment or cause other adverse effects.[22,64] Furthermore, when diuretics are given acutely in combination with other antihypertensive agents, profound hypotension can occur.

The immediate value of diuretics in acute HF is related more to their hemodynamic effects (venodilation) than to diuresis. Venodilation after IV diuretic administration decreases right-sided cardiac filling pressures, decreases pulmonary artery and wedge pressures, and increases cardiac output before diuresis occurs.[65] The presence of HF and severely elevated BP in M.R. warrants IV administration of a loop diuretic (e.g., furosemide 40 mg, torsemide [Demadex] 10–20 mg, or bumetanide [Bumex] 1 mg).

Dosing and Administration

CASE 16-2, QUESTION 4: What dose of nitroprusside should be used initially?

Effective infusion rates range from 0.25 to 10 mcg/kg/minute.[66,67] For M.R., an infusion of nitroprusside should be initiated at a rate of 0.25 mcg/kg/minute. The dose should be increased slowly by 0.25 mcg/kg/minute every 5 minutes until the desired pressure is achieved. A maximum infusion rate of 10 mcg/kg/minute has been recommended. If adequate BP reduction is not achieved within 10 minutes after maximal dose infusion, nitroprusside should be discontinued.[4] The dosage must be individualized according to patient response using continuous intraarterial BP recording and observing for signs or symptoms of toxicity.

Nitroprusside decomposes on exposure to light, so the solution should be shielded with an opaque sleeve. It is not necessary to protect the tubing from light. Reconstituted solutions are stable for 24 hours at room temperature. A change in the solution's color from light brown to dark brown, green, orange, or blue indicates a loss in activity. The solution should be discarded if this change occurs.

Therapeutic End Point

CASE 16-2, QUESTION 5: A nitroprusside infusion is started. What is the goal of therapy?

For most patients BP should be reduced by no more than 25% within the first minutes to hour, then if stable, therapy can be titrated to achieve a goal BP of 160/100 mm Hg during the next 2 to 6 hours. BPs can be reduced to near-normal levels within 8 to 24 hours. However, because M.R. has cerebral occlusive disease (carotid bruits), excessive reduction of his BP should be avoided. Overly aggressive reduction of BP in the presence of major cerebral vessel stenosis may decrease cerebral blood flow and produce strokes or other neurologic complications.

Normal cerebral blood flow remains relatively constant over a wide range of systemic BP measurements through autoregulatory mechanisms.[40,68] The autoregulatory effects can prevent large alterations in cerebral blood flow from either slow or rapid changes in systemic arterial pressures. In addition, the arterial BP required to maintain cerebral perfusion is higher in hypertensive patients than in normotensive individuals. If M.R.'s BP is reduced excessively, cerebral blood flow may decrease sharply. Therefore, a DBP of 100 to 105 mm Hg would be a reasonable initial therapeutic goal for him in the first 6 hours. If hypotension occurs, nitroprusside should be discontinued and M.R. should be placed in the Trendelenburg position, in which the head is kept lower than the trunk.

Cyanide Toxicity

CASE 16-2, QUESTION 6: M.R. is being treated with nitroprusside. However, during the last 36 hours, dose titration to 7 mcg/kg/minute has been necessary to control his BP. His tachycardia angina have resolved. Is he at risk of developing cyanide toxicity? What indices of toxicity should be monitored? Are there agents available to prevent toxicity?

A major concern when using sodium nitroprusside is toxicity secondary to the accumulation of its metabolic by-products, cyanide, and thiocyanate. Sodium nitroprusside decomposes within a few minutes after IV infusion. Free cyanide, which represents 44% of nitroprusside by weight, is released into the bloodstream, producing prussic acid (hydrogen cyanide), which is responsible for the acute toxicity.[69] The amount of hydrogen cyanide released is dose related.[70] Endogenous detoxification of cyanide occurs through a mitochondrial rhodanese system, which, in the presence of a sulfur donor such as thiosulfate, converts cyanide to thiocyanate.[69] Theoretically, cyanide can be expected to accumulate in the body when the rate of the sodium nitroprusside infusion exceeds 2 mcg/kg/minute for a prolonged period. The presence of hepatic or renal impairment may also predispose the patient to cyanide toxicity.[71,72]

Symptomatic cyanide toxicity occurs infrequently; however, several deaths have been reported after the use of sodium nitroprusside.[73] Cyanide toxicity occurs most commonly when large doses (total dose 1.5 mg/kg) of nitroprusside are administered rapidly to patients undergoing a surgical procedure that requires induction of hypotension. However, cyanide toxicity and mortality

---

associated with nitroprusside exceed 3,000 and 1,000 cases per year, respectively, according to two sources.[73,74]

Although concurrent sodium thiosulfate administration has been recommended in high-risk patients, no clinical data are available to indicate that it reduces overall mortality.[75] Furthermore, this intervention may result in the accumulation of thiocyanate, particularly if sodium thiosulfate is given at high infusion rates or to patients with renal insufficiency. Hydroxocobalamin has also been used to reduce the risk of cyanide toxicity secondary to nitroprusside infusions, but its use is limited because of poor availability and cost considerations.[72] With the availability of safer alternatives (e.g., fenoldopam, IV labetalol, IV nicardipine) for use in high-risk patients, the use of hydroxocobalamin or thiosulfate is rarely required.

Cyanide toxicity can be detected early by monitoring M.R.'s metabolic status. Lactic acidosis is an early indicator of toxicity because the progressive inactivation of cytochrome oxidase by cyanide results in increased anaerobic glycolysis.[76,77] A low plasma bicarbonate concentration and low pH, accompanied by an increase in the blood lactate or lactate-to-pyruvate ratio could indicate cyanide toxicity.[77] Additional signs of cyanide intoxication include tachycardia, altered consciousness, coma, convulsions, and the occasional smell of almonds on the breath.[70,77] Measuring serum thiocyanate levels is of no value in detecting the onset of cyanide toxicity. If toxicity develops, the infusion should be stopped and appropriate therapy for cyanide intoxication instituted. The need for such a high-dose infusion of nitroprusside to maintain M.R.'s pressure may increase his risk for cyanide toxicity, warranting close monitoring of his acid–base balance.

Thiocyanate Toxicity

CASE 16-2, QUESTION 7: Explain the difference between cyanide toxicity and thiocyanate toxicity. What is M.R.'s risk for thiocyanate toxicity if he is continued on a dose of 7 mcg/kg/minute? Is monitoring of serum thiocyanate concentrations necessary?

Sodium nitroprusside is more likely to produce thiocyanate toxicity. Although this complication is also rare, patients with renal impairment who receive infusions beyond 72 hours are particularly susceptible. Conversion of cyanide to thiocyanate, via sulfation by the liver, proceeds relatively slowly. The half-life of thiocyanate is 2.7 days with normal renal function and up to 9 days in patients with renal failure.[78] When sodium nitroprusside is infused for several days at moderate dosages (2–5 mcg/kg/minute), toxic levels of thiocyanate can occur within 7 to 14 days in patients with normal renal function and 3 to 6 days in patients with severe renal disease.[69]

Thiocyanate causes a neurotoxic syndrome manifested by psychosis, hyperreflexia, confusion, weakness, tinnitus, seizures, and coma.[71,78] Prolonged exposure to thiocyanate can suppress thyroid function through inhibition of iodine uptake and binding by the thyroid gland.[78] Measurement of blood levels of thiocyanate is only recommended in patients with renal disease or when the duration of the nitroprusside infusion exceeds 3 or 4 days. Nitroprusside should be discontinued if serum thiocyanate levels exceed 10 to 12 mg/dL.[79,80] Life-threatening toxicity is of concern when blood thiocyanate levels exceed 20 mg/dL. In emergency cases, thiocyanate can be readily removed by hemodialysis.[78]

For M.R., the potential for thiocyanate toxicity is low because his renal function is normal and the anticipated infusion duration is relatively short. Therefore, measurement of thiocyanate levels is not indicated.

Other side effects associated with nitroprusside therapy include nausea, vomiting, diaphoresis, nasal stuffiness, muscular twitching, dizziness, and weakness. These effects are usually acute and occur when nitroprusside is administered too rapidly. They can be reversed by decreasing the infusion rate.

CASE 16-2, QUESTION 8: M.R.'s serum chemistries and arterial blood gas values indicate a metabolic acidosis. Should the nitroprusside infusion be continued at 7 mcg/kg/minute? What alternatives are available?

Although the duration of M.R.'s nitroprusside therapy has been short, tolerance to the antihypertensive effect requires the use of a high-dose infusion to maintain BP control. Thus, acidosis may represent toxicity as a result of cyanide accumulation. The nitroprusside infusion should be discontinued at this time, and another rapidly acting, easily titratable parenteral antihypertensive such as fenoldopam or IV nicardipine should be initiated.

FENOLDOPAM

CASE 16-2, QUESTION 9: What are the advantages and disadvantages of fenoldopam compared with sodium nitroprusside?

Fenoldopam is a parenteral, rapidly acting, peripheral dopamine-1 agonist used to manage hypertensive crisis when a rapid reduction in BP is required.[81–84] Stimulation of the dopamine-1 receptors vasodilates coronary, renal, mesenteric, and peripheral arteries.[85,86] Fenoldopam has been used to control perioperative hypertension in patients undergoing cardiac bypass surgery.[87] The use of low-dose fenoldopam had been evaluated in those with acute kidney injury following cardiac surgery; therapy was not associated with a reduced risk of renal replacement therapy or 30-day mortality.[88] This refutes prior theories that dilation of the renal arteries with fenoldopam may reduce the risk of renal complications.[62,86]

Fenoldopam is as effective as sodium nitroprusside for treatment of hypertensive emergencies and does not cause either cyanide or thiocyanate toxicity.[57–59] Fenoldopam can be considered as an alternative to nitroprusside in patients who are at high risk for cyanide or thiocyanate toxicity. Over the past several years, the use of fenoldopam as an antihypertensive has decreased.[20]

Clearance of fenoldopam is not altered by renal or liver disease. Like nitroprusside, fenoldopam also has a short duration of action, with an elimination half-life of approximately 5 minutes, thus allowing for easy titration.[83,89] BP and heart rate should be frequently to avoid hypotension and dose-related reflex tachycardia. Flushing and headache may occur. Serum potassium should be monitored and repleted as necessary. Fenoldopam should be used cautiously in patients with glaucoma or intraocular hypertension due to a dose-dependent increase in intraocular pressure.[90,91]

CASE 16-2, QUESTION 10: Which antihypertensive agents should be avoided in M.R.? Why?

Labetalol, a potent, rapidly acting antihypertensive with both α- and β-blocking activity, is very effective in the treatment of hypertensive emergencies,[91–98] but it should not be used in M.R. Hemodynamically, labetalol reduces peripheral vascular resistance (afterload), BP, and heart rate, with almost no change in the resting cardiac output or stroke volume.[99]

M.R. was experiencing chest pain, and had tachycardia on admission; these signs and symptoms are most likely caused by his severely elevated BP and the presence of acute left ventricular failure. Even though labetalol may have alleviated M.R.'s angina, the negative inotropic action could acutely compromise his left ventricular dysfunction, an effect that outweighs the potential benefit of afterload reduction. In addition, even though labetalol is one of the safest β-blocking drugs when used in patients with asthma,[100] β-blocker therapy should be avoided as initial treatment in patients with asthma. Labetalol should be used only if alternative methods of reducing M.R.'s pressure fail.

LABETALOL

CASE 16-3

QUESTION 1: C.M., a 52-year-old Caucasian man, is admitted to the hospital with a 3-day history of increasing exertional substernal chest pain (without shortness of breath), diaphoresis, nausea, and vomiting. His history is significant for poorly controlled hypertension, glaucoma, and angina pectoris. Prior medications include dorzolamide ophthalmic drops, atenolol, hydrochlorothiazide, and oral nitrates. Physical examination reveals an anxious man who is alert and oriented. He has a BP of 210/146 mm Hg without orthostasis and a regular pulse of 115 beats/minute. Bilateral hemorrhages and exudates are present on funduscopic examination. The lungs are clear and the point of maximal impulse is displaced. There are no murmurs or gallops. Examination of the abdomen is unremarkable, and there is no peripheral edema. The neurologic examination is normal.

Significant laboratory values include the following:

Urea nitrogen, 49 mg/dL

Serum creatinine, 2.8 mg/dL

Serum creatinine was previously noted to be 1.2 mg/dL. Urinalysis shows proteinuria and hematuria. The electrocardiogram demonstrates sinus tachycardia with left-axis deviation, left ventricular hypertrophy, and nonspecific ST-T wave changes. The chest radiograph reveals mild cardiomegaly.

C.M. is given nitroglycerin sublingually and 1 inch of nitroglycerin ointment is applied topically. He is started on IV labetalol. Is this choice of treatment reasonable, considering C.M.'s angina and acute kidney injury?

The presence of chest pain, retinopathy, and new-onset renal disease, as well as the magnitude of the BP elevation in C.M., classifies his presentation as a hypertensive emergency that warrants a prompt reduction in BP. Sublingual and topical nitroglycerin may help in acutely and temporarily lower his BP and relieve his chest pain while waiting for more definitive treatment to be implemented.

IV labetalol has been used successfully in hypertensive emergencies.[92–98] Labetalol blocks both β- and α-adrenergic receptors and also may exert a direct vasodilator effect. The β-blockade is nonselective with β- to α-potency of 3:1 for oral and 7:1 for IV. Labetalol is advantageous in C.M. because the immediate onset of action will reduce peripheral vascular resistance without causing reflex tachycardia. Myocardial oxygen demand will be reduced and coronary hemodynamics will be improved, making this agent an excellent choice for patients such as C.M., with anginal symptoms or MI. In addition, IV labetalol does not significantly reduce cerebral blood flow; therefore, it may be useful in patients with cerebrovascular disease.[1,23]

Fenoldopam or nitroprusside could also be used to treat C.M. Fenoldopam could be considered, but C.M.'s history of glaucoma would preclude its use. Additionally, fenoldopam would not be preferred due to the potential for reflex tachycardia and risk of worsening ischemia. Treatment with nitroprusside would expose C.M. to the potential risk of cyanide and thiocyanate toxicity with his new-onset acute kidney injury. In contrast, labetalol has been used successfully in patients with renal disease without deleterious side effects.[101,102] Labetalol is eliminated by glucuronidation in the liver, with less than 5% of the dose being excreted unchanged in the urine.

Contraindications and Precautions

CASE 16-3, QUESTION 2: What cautions should be exercised when using labetalol in C.M.?

Labetalol's disadvantages are primarily related to its β-blocking effects. Therefore, it should not be used in patients with asthma, heart block greater than first degree, or sinus bradycardia, and it should be used with caution in patients with decompensated HF[93,97,103] (see Case 16-2, Question 10). None of these are present in

C.M. Like other β-blockers, labetalol should also be used with caution in patients with β.[104] Labetalol has been effective in the treatment of hypertension associated with pheochromocytoma and excess catecholamine states as well as those with rebound hypertension from β-blocker withdrawal.[105] However, because labetalol is primarily a β-blocker, paradoxic hypertension may occur in patients with pheochromocytoma. These individuals have adrenal tumors that excrete high amounts of norepinephrine, which results in relatively unopposed α-receptor stimulation.[106] More clinical experience is required before labetalol can be recommended in patients with pheochromocytoma.[6,92]

CASE 16-3, QUESTION 3: How should parenteral labetalol be given to C.M.?

IV labetalol can be given by pulse administration or continuous infusion.[92–97] Bolus injections are administered, beginning with 20 mg given over 2 minutes, followed by 40 to 80 mg every 10 to 15 minutes until the desired response is achieved or a cumulative dose of 300 mg is reached. The desired response is usually achieved with a mean dose of 200 mg in 90% of patients.[93] The maximal effect occurs within 10 minutes,[95] and the antihypertensive response may persist for more than 6 hours.[107] Because the rate of BP reduction is accelerated with an increase in infusion rate,[95] a controlled continuous infusion may provide a more gradual reduction in arterial pressure with less frequent adverse effects.[97,108] The infusion can then be started at a rate of 2 mg/minute and titrated until a satisfactory response is achieved or until a cumulative dose of 300 mg is reached.

Parenteral to Oral Conversion

CASE 16-3, QUESTION 4: C.M. was treated with a labetalol infusion and required a cumulative dose of 180 mg to achieve a DBP of 100 mm Hg. His anginal symptoms resolved almost immediately, but 3 hours after the infusion, C.M. became faint and dizzy while ambulating. Should oral labetalol be withheld in C.M.?

Postural hypotension and dizziness are dose related and more commonly associated with the IV route of administration.[99,103] C.M. should remain in a supine position after the IV administration of labetalol, and his ability to tolerate an upright position should be established before permitting ambulation. Oral labetalol can be given to C.M. when his symptoms resolve. There is no correlation between the oral maintenance dose and the total initial IV dose. C.M. should be started on an empiric dose of 100 to 200 mg of oral labetalol 2 to 3 times per daily, and this should be titrated as necessary.

CASE 16-3, QUESTION 5: What other side effects can occur with labetalol therapy?

Other side effects commonly associated with labetalol include nausea, vomiting, abdominal pain, and diarrhea in up to 15% of the patients.[103] Scalp tingling is an unusual side effect that has been reported in a few patients after IV administration; it tends to disappear with continued treatment. Other side effects include tiredness, weakness, muscle cramps, headache, and skin rashes.

NITROGLYCERIN

CASE 16-3, QUESTION 6: Would parenteral nitroglycerin be an acceptable alternative to labetalol for C.M.?

Hypertensive emergencies in the setting of unstable angina or MI requires an immediate reduction in BP. Nitroprusside has been used successfully, but IV nitroglycerin can have more favorable effects on collateral coronary flow in patients with ischemic heart disease.[109] By diminishing preload, nitroglycerin decreases left ventricular diastolic volume, diastolic pressure, and myocardial wall tension, thus reducing myocardial oxygen consumption.[110] These changes favor redistribution of coronary blood flow to the subendocardium, which is more vulnerable to ischemia. At high dosages, nitroglycerin dilates arteriolar smooth muscles, and this reduction in afterload also decreases myocardial wall tension and oxygen consumption.[111]

IV nitroglycerin has a rapid onset of action and a short duration, and is easily titratable. It is generally appropriate to begin IV nitroglycerin in the dose range of 5 to 10 mcg/minute, increased as needed to control pressure and symptoms. The usual dose is in the range of 40 to 100 mcg/minute. The major limiting side effects are headache and the development of tolerance. In general, IV nitroglycerin is well suited for use in patients such as C.M. who have angina or in patients who have hypertensive emergency associated with MI or coronary artery bypass surgery.

HYDRALAZINE

CASE 16-4

QUESTION 1: T.M., a 30-year-old Caucasian man with a history of chronic glomerulonephritis and poorly controlled hypertension, came to the emergency department complaining of early morning occipital headaches during the past week. He has no other complaints. He has not taken any BP medication in a month. Physical examination revealed an afebrile man in no acute distress with a BP of 160/128 mm Hg without orthostasis and a regular pulse of 90 beats/minute. Funduscopic examination revealed bilateral exudates without hemorrhages or papilledema. The lungs were clear. Cardiac examination was pertinent for cardiomegaly and an S_4 gallop. The remainder of the physical workup was normal.

Laboratory results include the following values:

Hematocrit, 32%
Blood urea nitrogen, 40 mg/dL
Serum creatinine, 2.5 mg/dL (baseline serum creatinine 1.9 mg/dL)
Bicarbonate, 18 mEq/L

Urinalysis reveals 2+ protein, 2+ hemoglobin with 4 to 10 red blood cells per high-power field. The electrocardiogram demonstrates normal sinus rhythm with left ventricular hypertrophy. The chest radiograph is unremarkable.

T.M.'s presentation meets criteria for a hypertensive emergency (i.e., DBP >120 mm Hg and presence of worsening renal function). IV antihypertensive therapy is required for T.M. T.M. was given 20 mg hydralazine IV, and a repeat BP after 1 hour was 150/100 mm Hg. What are the advantages and disadvantages of parenteral hydralazine, and when should it be used to acutely lower BP?

Hydralazine is a direct vasodilator that reduces total peripheral resistance through relaxation of the arterial smooth muscle. It is rarely used to treat hypertensive emergencies because its antihypertensive response is less predictable than that of other parenteral agents. Additionally, hydralazine has a prolonged half-life, which can be problematic if too fast correction or hypotension occurs.[22] It is not consistently effective in controlling crises associated with essential hypertension.

Contraindications

Hydralazine should not be used in patients with coronary heart disease because the reflex tachycardia causes an increase in myocardial oxygen demand, which may result in the development or worsening of ischemic symptoms. In addition, hydralazine should be avoided in patients with aortic dissection because of its reflex cardiostimulating effect. In contrast, hydralazine can be useful in patients such as T.M., who have chronic renal failure because the reflex increase in cardiac output is accompanied by an increase in organ perfusion.[21]

Dosing and Administration

Parenteral hydralazine should be considered an intermediate treatment between oral agents and more aggressive therapy with such agents as fenoldopam or nitroprusside. It can be given IV or intramuscularly. The onset of action develops slowly over 20 to 40 minutes, thus minimizing the risk of acute hypotension. Parenteral doses are considerably lower than oral doses because of increased bioavailability.

OTHER PARENTERAL DRUGS

CASE 16-4, QUESTION 2: Are there alternatives to hydralazine for parenteral treatment of hypertensive crisis?

Intravenous Enalaprilat

Enalaprilat, the active metabolite of the oral prodrug enalapril, is approved by the U.S. Food and Drug Administration for the treatment of hypertension when oral therapy is not feasible. However, enalaprilat has been used to treat severe hypertension.[112–117] The initial dose is 0.625 to 1.25 mg IV and can be repeated every 6 hours, if necessary. To minimize the risk of hypotension, the initial doses should not exceed 0.625 mg in patients receiving diuretics or in patients with clinical evidence of hypovolemia. The onset of action is within 15 minutes, but the maximal effect may take several hours. Because only 60% of the patients respond to BP reduction within 30 minutes, it cannot be reliably used to acutely lower pressure in hypertensive emergencies.[115] Although higher initial doses have been successfully used to achieve BP control,[116] some evidence indicates that doses greater than 0.625 mg do not significantly alter the magnitude of enalaprilat's antihypertensive effect.[114] Enalaprilat is also beneficial in patients with HF. Precautions for the use of enalaprilat are similar to those of captopril (see Case 16-1, Question 5). Because of the prolonged time required to achieve an adequate response, limited clinical experience, and variable response rates (especially in African Americans), enalaprilat cannot be recommended for the routine treatment of patients with hypertensive emergencies.[115,117]

Intravenous Calcium-Channel Blockers

CASE 16-5

QUESTION 1: H.C. is a 71-year-old Caucasian man undergoing urgent coronary artery bypass graft surgery after a MI. H.C. has a history of a cerebrovascular accident and chronic kidney disease (serum creatinine is stable at 1.6 mg/dL). Two hours after surgery H.C.'s BP increased from 142/90 to 170/132 mm Hg. H.C. was administered IV nicardipine postoperatively for BP control. Is nicardipine an appropriate choice for H.C.?

Nicardipine

Postoperative hypertension is typically short lived and is most commonly seen after neurosurgical, head and neck, vascular, and cardiothoracic procedures (as is the case with H.C.). Treatment is typically only required for 6 hours postoperatively, and up to

---

24 to 48 hours for some who may have persistent hypertension. Adequate control of BP postoperatively is necessary to minimize the risk of cardiovascular, neurologic, or surgical-site complications such as bleeding.[118] When selecting an agent, one should consider therapies with a quick onset and short duration of action as well as established efficacy and safety in the postoperative setting.

Nicardipine is a potent cerebral and systemic vasodilator and a useful therapeutic option in the management of severe hypertension. Its onset of action is within 1 to 2 minutes, and its elimination half-life is 40 minutes.[119] Hemodynamic evaluations demonstrated that IV nicardipine significantly decreased mean arterial pressure and systemic vascular resistance and significantly increased cardiac index with little or no change in heart rate.[120] As a dihydropyridine, nicardipine has less negative inotropic activity compared with nondihydropyridines. Titratable IV nicardipine has been studied extensively for use in controlling postoperative hypertension[120–123] and hypertensive emergencies.[124–127]

In the treatment of postoperative hypertension,[120] IV nicardipine was administered as an infusion titrated in the following manner: 10 mg/hour for 5 minutes, 12.5 mg/hour for 5 minutes, and 15 mg/hour for 15 minutes, followed by a maintenance infusion of 3 mg/hour thereafter. The mean response time and infusion rate were 11.5 minutes and 12.8 mg/hour, respectively. The most commonly reported adverse effects included hypotension, tachycardia, and nausea and vomiting.

In studies of patients receiving nicardipine versus nitroprusside for postoperative hypertension after cardiac endarterectomy and coronary artery bypass grafting, breakthrough BP was controlled more rapidly with nicardipine and required fewer overall dose titrations. In addition, nicardipine was well tolerated and did not lead to an increased risk of complications.[128,129]

Nicardipine is an appropriate choice of therapy for H.C. in the postoperative setting because this agent has a rapid onset of action, and provides sustained BP control during the infusion period. It is easily titratable, with a predictable response, and is relatively free of severe adverse effects. Therapy should be titrated to achieve a BP approximately 10% higher than the patient's baseline. In addition to nicardipine, nitroprusside, nitroglycerin, and labetalol are most commonly used to manage postoperative hypertension.[118] Finally, nicardipine may be useful in patients with cerebral insufficiency or peripheral vascular disease. Because of the potential for reflex tachycardia, it should be used with caution in patients with ongoing coronary ischemia.

Nicardipine has been proven effective in multiple studies of populations with hypertensive emergencies, and, as a dihydropyridine, has less negative inotropic activity compared with nondihydropyridines.

In contrast, the nondihydropyridines parenteral verapamil and diltiazem, although clinically effective for prompt lowering of BP, have not been extensively studied in patients with hypertensive emergencies. Clevidipine, a third-generation dihydropyridine, has also been shown to be useful in controlling BP in hypertensive emergencies and in the perioperative setting.

CASE 16-5, QUESTION 2: What other IV forms of calcium-channel blockers are available? Would any of these agents be an appropriate choice of therapy for H.C.?

Nondihydropyridines

IV verapamil (5–10 mg) produces a significant reduction in BP, which occurs within 15 minutes and persists for 6 to 8 hours. As a cardiovascular drug, it is primarily used as a rate-controlling agent in the treatment of supraventricular tachycardias.

IV diltiazem is approved for temporary control of the ventricular rate in atrial fibrillation or atrial flutter and for rapid conversion of paroxysmal supraventricular tachycardia.[130–132] Parenteral diltiazem has also been used to control hypertension that occurs intraoperatively and postoperatively,[133,134] and in patients with an acute coronary syndrome.[135,136] However, published experience with the use of IV diltiazem for the treatment of severe hypertension is limited.[137,138]

Atrioventricular nodal conduction abnormalities can occur during administration of IV verapamil or diltiazem. Patients receiving either of these therapies require continuous monitoring by electrocardiogram and frequent BP checks. IV verapamil and diltiazem should be avoided in patients with sick sinus syndrome or advanced degrees of heart block. Until additional information is available, caution should be exercised in using either agent parenterally to lower BP acutely. In addition, use of nondihydropyridines should be avoided when acutely treating any hypertensive patient with concomitant systolic HF owing to their negative inotropic effects.

CASE 16-5, QUESTION 3: What factors should clinicians consider before recommending the use of clevidipine?

Clevidipine

Clevidipine is another IV dihydropyridine calcium-channel blocker with arterial-selective vasodilation properties.[139] Clevidipine is quickly metabolized in extravascular tissue and blood by esterases, leading to a short elimination half-life of 1 minute[140] and complete resolution of hemodynamic effects within 10 minutes after the end of a 24-hour continuous infusion.[141] Clevidipine demonstrates a quick onset of action of 1 to 2 minutes.[142] These pharmacokinetic and pharmacodynamic properties make it an attractive agent for managing hypertensive emergencies. Clevidipine demonstrated efficacy in the treatment of hypertension in both preoperative and postoperative cardiac surgery patients.[143,144] In this setting, therapy was initiated at a rate of 0.4 mcg/kg/minute. Target BP was a reduction of at least 15% from baseline. The dose was titrated every 90 seconds by doubling the dose up to an infusion rate of 3.2 mcg/kg/minute, then increasing the dose by 1.5 mcg/kg/minute to a maximum rate of 8 mcg/kg/minute. Clevidipine demonstrated a median time of effectiveness within 6 minutes in greater than 90% of the patients who received the study medication.

Clevidipine has been compared with nitroglycerin, nitroprusside, and nicardipine in the management of perioperative hypertension in cardiac surgery patients.[139] Clevidipine was more effective in maintaining patients within a predefined BP target range when compared individually with nitroglycerin and nitroprusside, but this did not translate to differences in clinical outcomes. Clevidipine was equivalent to nicardipine in keeping patients within a prespecified BP range. The incidence and severity of adverse events were similar among patients who received clevidipine and comparison agents.

Based on the limited data, nondihydropyridines would not be an appropriate choice of therapy for H.C. Additionally, IV verapamil has a long duration of action, which is not an ideal characteristic in the setting of postoperative hypertension. Clevidipine, however, has a rapid onset of action and short duration of action and is effective in controlling BP in the perioperative setting.

Clevidipine infusions can induce reflexive tachycardia with an increased heart rate by up to approximately 20 beats/minute.[141] Clevidipine is formulated in a 20% lipid emulsion, so it should be avoided in patients with serum triglycerides greater than 400 mg/dL, and any remaining drug should be discarded after 4 hours of use. Clevidipine is contraindicated in patients with allergies to soybeans, soy products, eggs, or egg products. This agent is also contraindicated in those with defective lipid metabolism or acute pancreatitis (if accompanied by hyperlipidemia), and in patients with severe aortic stenosis.[142]

Aortic Dissection

TREATMENT

CASE 16-6

QUESTION 1: B.S., a 68-year-old Caucasian man with a long history of hypertension and nonadherence, presents to the local emergency department complaining of the sudden onset of severe, sharp, diffuse chest pain that radiates to his back between his shoulder blades. Significant findings on physical examination include a pulse of 100 beats/minute, BP of 200/120 mm Hg, clear lungs, and an S_4 without murmurs. The laboratory data are unremarkable. The electrocardiogram results are interpreted as sinus tachycardia with left ventricular hypertrophy, but no acute changes are noted. The chest radiograph is significant for widening of the mediastinum. An emergency chest computed tomography scan reveals a dissection at the arch of the aorta. What antihypertensive medication(s) would be most appropriate for B.S., and why?

Dissection of the aorta occurs when the innermost layer of the aorta (the intima) is torn such that blood enters and separates its layers. The ultimate treatment for this type of hypertensive emergency depends on its location and severity; however, the first principle of therapy is to control any existing hypertension with agents that do not increase the force of cardiac contraction or heart rate. This lessens the force that the cardiac impulse transmits to the dissecting aneurysm.

The aim of antihypertensive therapy in aortic dissection is to lessen the pulsatile load or aortic stress by lowering the BP. Reducing the force of left ventricular contractions, and consequently the rate of rise of aortic pressure, retards the propagation of the dissection and aortic rupture.[145,146] The treatment of choice for aortic dissection has classically been a vasodilatory agent such as sodium nitroprusside, fenoldopam, or nicardipine in combination with a β-blocker titrated to a heart rate of 55 to 65 beats/minute.[145,147] Labetalol monotherapy has been used as an alternative.[148] These drugs decrease BP, venous return, and cardiac contractility, thus decreasing sheer stress to the aorta.

One common regimen is a combination of IV sodium nitroprusside (0.5–2 mcg/kg/minute) plus IV esmolol.[20,146] This combination can be used as initial therapy for B.S. The concurrent administration of a β-blocking agent with a vasodilator is desirable because the latter may induce reflex tachycardia in response to vasodilation.

Esmolol is a parenteral cardioselective β_1-blocker with a rapid onset and short duration of action. For the management of hypertension, esmolol should be given as a loading dose of 250 to 500 mcg/kg over 1 minute, followed by a maintenance infusion of 50 to 300 mcg/kg/minute. Irritation, inflammation, and induration at the infusion site occur in 5% to 10% of patients.

Hypotension is the most commonly reported adverse event and is directly related to the duration of esmolol administration.[149] However, because of the short half-life, resolution of hypotension occurs within 30 minutes of discontinuing the infusion. Direct vasodilators such as hydralazine should be avoided because they increase stroke volume and left ventricular ejection rate. These effects augment the pulsatile flow and accentuate the sharpness of the pulse wave. This increases mechanical stress on the aortic wall and may lead to further dissection.[20]

Depending on the location of the dissection, surgical intervention may be required.[147,150] However, until a definitive diagnosis is made, the primary goal is to reduce the BP and myocardial contractility to the lowest level compatible with the maintenance of adequate renal, cerebral, and cardiac perfusion.[20] Aggressive BP control is warranted to minimize target organ damage and to prevent further dissection or hemorrhage.[146] For aortic dissection, it is suggested that the systolic BP should be lowered to 100 to 120 mm Hg or a mean arterial pressure of less than 80 mm Hg within 5 to 10 minutes.[20]

Shock

Jason S. Haney

	CORE PRINCIPLES	CHAPTER CASES
1	Shock is a syndrome with multiple etiologies characterized by an impairment of tissue perfusion.	
2	The impairment of tissue perfusion, regardless of cause, can lead to cellular dysfunction, organ failure, and death.	
3	The diagnosis of shock is made by the findings of impaired tissue perfusion on physical examination, and hemodynamic and laboratory changes consistent with impaired perfusion. Hypotension may or may not be present. Hemodynamic monitoring is vital for the determination of the type of shock and assessment of response to interventions.	**Case 17-1 (Questions 1 and 6), Case 17-2 (Questions 1, 4 and 6), Case 17-3 (Questions 1-2), Tables 17-2 and 17-3, Figure 17-1**
4	Hypovolemic shock is caused by a reduction in intravascular volume, which results in changes in the hemodynamic profile such as decreases in blood pressure, central venous pressure, pulmonary capillary wedge pressure, and cardiac output, and a compensatory increase in heart rate, systemic vascular resistance, and myocardial contractility.	**Case 17-1 (Question 1), Case 17-2 (Questions 1-2)**
5	Resuscitation is required to treat hypovolemic shock to maintain adequate tissue perfusion and oxygenation. This can be achieved by administration of intravenous crystalloids, colloids, or blood.	**Case 17-1 (Questions 2-7), Case 17-2 (Questions 3-6)**
6	The physiologic response to fluid loss or gain is described by the Frank–Starling curve.	**Case 17-2 (Questions 3, 4), Figure 17-3**
7	Cardiogenic shock results from a decrease in the heart's ability to maintain cardiac output that is unrelated to hypovolemia.	**Case 17-3 (Questions 1-2)**
8	Treatment of patients in cardiogenic shock involves optimization of preload, increasing contractility, and reducing afterload if the blood pressure permits.	**Case 17-3 (Questions 3-8), Figure 17-4**
9	Septic shock is a type of distributive shock characterized by a profound vasodilatory response and decrease in blood pressure.	**Case 17-4 (Question 1)**
10	Treatment of septic shock involves stabilization with fluids, vasopressors, and inotropic agents and treatment of the underlying condition. Other	**Case 17-4 (Questions 2-7)**

therapies involve modification of the body's response to infection.	
⑪ Patients with sepsis can experience disseminated intravascular coagulation, which can lead to hemorrhagic and thrombotic complications.	**Case 17-4 (Questions 8-11), Figure 17-5**

INTRODUCTION

Shock is defined in simple terms as a syndrome of impaired tissue perfusion and oxygenation usually, but not always, accompanied by hypotension. This impairment of tissue perfusion eventually leads to cellular dysfunction, followed by organ damage and death if untreated. The most common causes of shock are situations that result in a reduction of intravascular volume (hypovolemic shock), myocardial pump failure (cardiogenic shock), or increased vascular capacitance (distributive shock). The type of treatment required depends on the etiology.

In recent years, medical support of patients with shock has improved because of better technologies for hemodynamic monitoring, recognition of the value of vigorous volume replacement, appropriate use of inotropic and vasoconstrictive agents, and the development of better ways to treat the underlying cause of the shock syndrome. Understanding the principles of shock should further enhance the prompt recognition of patients at risk, rapid initiation of corrective measures, and development of innovative treatment regimens.

CAUSES

Shock is common among intensive care unit (ICU) patients and is present in up to one-third of ICU admissions.[1] Table 17-1 outlines the classification of shock and precipitating events.[2] Recognition of the etiology and underlying pathology of the various forms of shock is essential for managing this condition. The distinctions among subtypes of shock only apply, however, in the relatively early stages. As the syndrome evolves and compensatory mechanisms are overwhelmed, it becomes increasingly difficult to determine the subtypes because the clinical and pathophysiologic features of advanced shock are the same for all. Also, different types of shock can occur at the same time (e.g., a patient with septic shock who is also hypovolemic). The mortality rate for shock remains quite high—as high as 60%

to 80% in severe cases—despite recent improvements in its early recognition and management.[1]

PATHOPHYSIOLOGY

Tissue perfusion is a complex process of oxygen and nutrient delivery as well as waste removal. When perfusion is impaired, it sets up a cascade of events that can eventually end in death. Although the etiology of shock is varied, the eventual progression (if untreated) to cell death and subsequent organ dysfunction results from a common pathway of ischemia, endogenous inflammatory cytokine release, and the generation of oxygen radicals. When cells are subjected to a prolonged period of ischemia, anaerobic metabolism begins. This inefficient process results in a decrease of adenosine triphosphate stores and causes the buildup of lactic acid and other toxic substances that can alter mitochondrial function and eventually result in cell death. In the advanced stages of shock, irreversible cellular damage leads to multiple organ system failure, also known as multiple organ dysfunction syndrome.

Table 17-1

Classification of Shock and Precipitating Events

Hypovolemic Shock
Hemorrhagic
Gastrointestinal bleeding (e.g., varices, peptic ulcer)
Trauma
Internal bleeding: ruptured aortic aneurysm, retroperitoneal bleeding, postoperative bleeding, hemorrhagic pancreatitis, postpartum hemorrhage
Nonhemorrhagic
Gastrointestinal losses: vomiting, diarrhea, external drainage
Renal losses: diabetes mellitus, diabetes insipidus, overuse of diuretics
Sequestration: ascites, third-space accumulation
Cutaneous: burns, nonreplaced perspiration, and insensible water losses
Cardiogenic Shock
Cardiomyopathic causes
Acute myocardial infarction (left or right ventricular infarction)
Low cardiac output syndrome
Myocarditis
End-stage cardiomyopathy or severe acute exacerbation of heart failure
Arrhythmogenic causes
Tachyarrhythmia (atrial fibrillation/flutter, reentrant tachycardia, ventricular tachycardia/fibrillation)

Bradyarrhythmia (Mobitz type II second-degree heart block, complete heart block)
Mechanical causes
Rupture of septum or free wall
Severe mitral or aortic valve insufficiency
Papillary muscle or chordae tendineae rupture or dysfunction
Critical aortic stenosis
Pericardial tamponade
Distributive Shock
Septic (bacterial, fungal, viral, parasitic, mycobacterial)
Non-septic
Anaphylactic
Neurogenic (spinal cord injury, traumatic brain injury, cerebral damage, severe dysautonomia)
Inflammatory (burns, trauma, pancreatitis, air/fat embolism, post-cardiopulmonary bypass)
Drug- or toxin-induced (anesthesia, ganglionic and adrenergic blockers, overdoses of barbiturates and narcotics, carbon monoxide, heavy metal, cyanide)
Endocrine (adrenal crisis, myxedema coma)

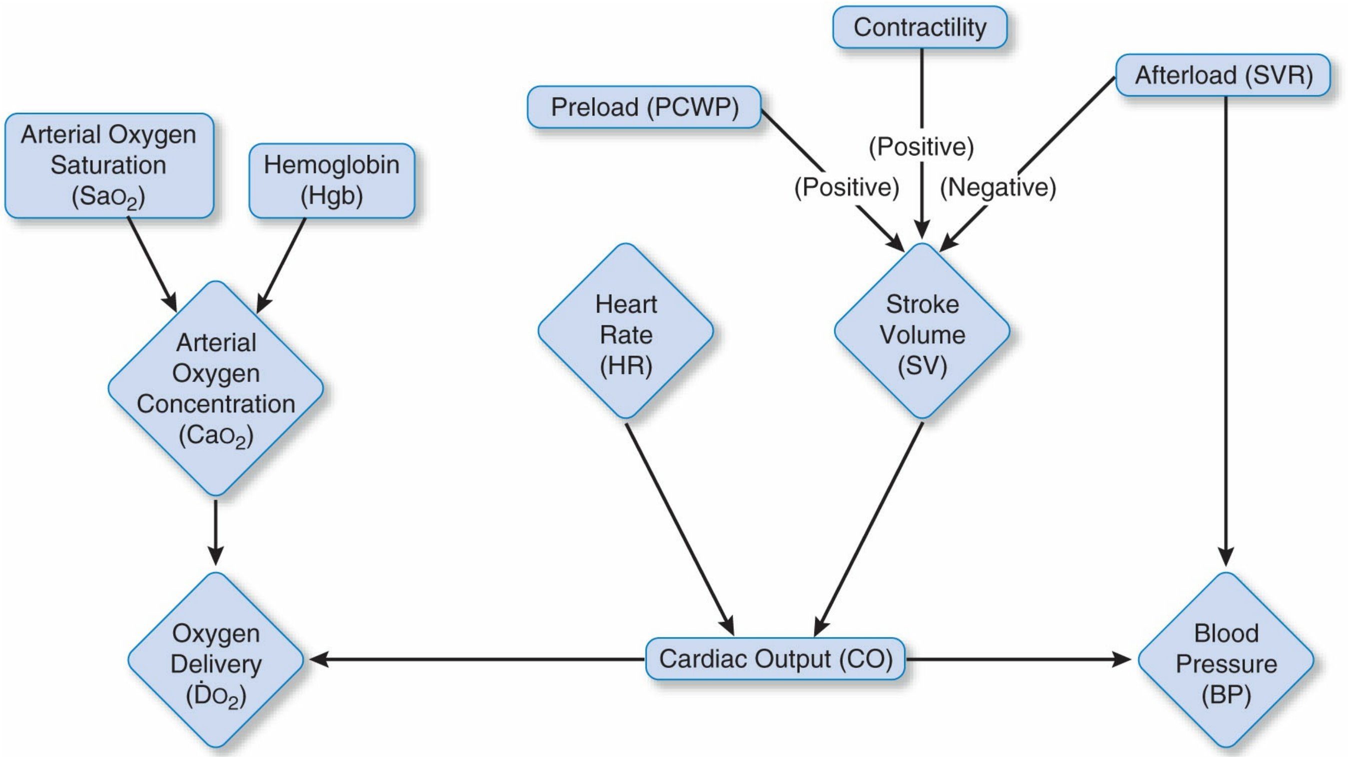
Adapted with permission from Gaieski D. Evaluation of and initial approach to the adult patient with undifferentiated hypotension and shock. In: Post TW, ed. UpToDate. Waltham, MA: Wolters Kluwer. Accessed July 1, 2015.

The body produces inflammatory cytokines in response to ischemia, injury, or infection. The phrase systemic inflammatory response syndrome (SIRS) is the recommended umbrella term to describe any acute, overwhelming inflammatory response, independent of the cause.[3] This syndrome has best been described in the sepsis literature; however, it can occur after a wide variety of insults, including hemorrhagic shock, infection (septic shock), pancreatitis, ischemia, multi-trauma and tissue injury, and immune-mediated organ injury. SIRS is usually a late manifestation of hypovolemic forms of shock. It is uncommon in cardiogenic shock but is the hallmark of septic shock. SIRS is clinically characterized by profound vasodilation, which impairs perfusion, increases capillary permeability, and can reduce intravascular volume.

CLINICAL PRESENTATION AND DIAGNOSIS

Independent of the pathophysiologic cause, the clinical syndrome of shock progresses through several stages. During each step, the body uses and exhausts various compensatory mechanisms to balance oxygen delivery ($D.O_2$) and oxygen consumption ($V.O_2$) in an effort to maintain perfusion of vital organs. Oxygen delivery is determined by the arterial concentration of oxygen multiplied by the blood flow (cardiac output [CO]) (Fig. 17-1 and Table 17-2). Normally, consumption is independent of supply, except at low rates of $\dot{D}O_2$. In some critically ill patients, perfusion is inadequate to meet metabolic demands and $\dot{V}O_2$ becomes dependent on the supply despite "normal" $\dot{D}O_2$ ranges.

Although hypotension is often described as the hallmark of shock, it is not necessarily present in all patients.



Contractility
Afterload (SVR)
Preload (PCWP)
(Positive)
(Positive)
(Negative)
Arterial Oxygen Saturation (Sa_{O_2})
Hemoglobin (Hgb)
Heart Rate (HR)
Stroke Volume (SV)
Arterial Oxygen Concentration (Ca_{O_2})
Oxygen Delivery ($\dot{D}_{O_2}$)
Cardiac Output (CO)
Blood Pressure (BP)

Figure 17-1 Determinants of blood pressure, cardiac output, and oxygen delivery.

Table 17-2

Normal Hemodynamic Values and Derived Indices

	Definition/Equation	Normal Value	Units
Directly Measured			
Blood pressure (BP) [systolic (SBP)/diastolic (DBP)]	Pressure in the central arterial bed, determined by cardiac output and systemic vascular resistance.	120–140/80–90	mm Hg
Cardiac output (CO)	Amount of blood ejected from the left ventricle per minute; determined by stroke volume and heart rate. CO = SV × HR	4–7	L/minute
Central venous pressure (CVP)[a]	Measures mean pressure in right atrium and reflects right ventricular filling pressure and volume status. Primarily determined by venous return	2–6	mm Hg[b]

	to the heart. The goal in most critically ill patients is 8–12 mm Hg.		
Heart rate (HR) (pulse)	Number of myocardial contractions per minute.	60–100	beats/minute

Pulmonary artery pressure (PAP)	Systolic (SPAP): Measures PAP during systole; reflects pressure generated by the contraction of the right ventricle. Diastolic (DPAP): Measures PAP during diastole; reflects diastolic filling pressure in the left ventricle. May approximate pulmonary capillary wedge pressure (PCWP); normal gradient <5 mm Hg between DPAP and PCWP. Mean (MPAP): Average measure of PAP during the entire cardiac cycle; mPAP ≥25 mm Hg at rest is defined as pulmonary hypertension.	20–30/8–12 (10–22)	mm Hg
Pulmonary capillary wedge pressure (PCWP)	Measures pressure distal to the pulmonary artery; reflects left ventricular filling pressures (preload). Usually lower than or within 5 mm Hg of pulmonary artery diastolic pressure (DPAP).	5–12[c]	mm Hg
Central venous oxygen saturation ($ScvO_2$)	The oxygen saturation of blood returning to the heart; a reflection of oxygen extraction from the upper body.	>70	%
Mixed venous oxygen saturation (SvO_2)	The oxygen saturation of blood in the pulmonary artery; a marker of the relationship between cardiac output and total body oxygen consumption.	>65	%
Derived Indices			
Cardiac index (CI)	Cardiac output per square meter of body surface area (BSA[d]). CI = CO/BSA	2.5–4.2	L/minute/m^2
Left ventricular stroke work index (LVSWI)	Amount of work the left ventricle exerts during systole; adjusted for body surface area (BSA[d]). A measure of contractility, the inotropic state of the myocardium. LVSWI = (MAP – PCWP) × SVI × 0.0136	35–85	g/m^2/beat
Mean arterial pressure (MAP)	MAP = [(2 × DBP) + SBP]/3	80–100	mm Hg

Oxygen delivery ($D.O_2$)	The amount of oxygen delivered by the body per unit time. $D.O_2 = CO \times CaO_2$ where $CaO_2 = Hgb \times SaO_2 \times 13.9$	700–1,200	mL/minute
Oxygen consumption ($V.O_2$)	The amount of oxygen consumed by the body per unit time. The product of cardiac output and the difference between the arterial and venous oxygen concentration. $V.O_2 = CO \times (CaO_2 - CvO_2)$ where $CvO_2 = Hgb \times SvO_2 \times 13.9$	200–400	mL/minute
Coronary artery perfusion pressure (CPP)	The pressure gradient between the coronary arteries and the pressure in either the right atrium or the left ventricle during diastole. A major determinant of coronary blood flow and oxygen supply to the heart. CPP = DBP – PCWP	60–80	mm Hg
Pulmonary vascular resistance (PVR)	Primary determinant of right ventricular afterload. PVR = [(MPAP – PCWP)/CO] × 74	20–120	dynes·s·cm^{-5}
Stroke volume (SV)	Amount of blood ejected from the ventricle with each systolic contraction. SV = CO/HR	60–130	mL/beat
Stroke volume index (SVI)	Stroke volume adjusted for body surface area (BSA[d]). SVI = SV/BSA	30–75	mL/beat/m^2
Systemic vascular resistance (SVR)	Measure of impedance applied by systemic vascular system to systolic effort of left ventricle; determined by autonomic nervous system and condition of vessels. Determinant of left ventricular afterload. SVR = [(MAP – CVP)/CO] × 74	800–1,440	dyne·s·cm^{-5}
Systemic vascular resistance index (SVRI)	SVR adjusted for body surface area (BSA[d]). SVRI = SVR × BSA	1,680–2,580	dyne·s·cm^{-5}·m^2

[a] CVP is essentially synonymous with RAP.

[b] 2–6 mm Hg = 3–6 cm H_2O (conversion: 1 mm Hg = 1.34 cm H_2O).

[c] May optimally ↑ PCWP to 16–18 mm Hg in critically ill patients.

[d] BSA, body surface area = 1.7 m^2 (average male).

The diagnosis of shock is based on the findings of impaired tissue perfusion on examination.[1] These findings may include the following:

- Systolic blood pressure (SBP) less than 90 mm Hg, mean arterial pressure (MAP) less than 65 mm Hg, or at least a 40 mm Hg decrease from baseline
- Tachycardia (heart rate [HR] greater than 90 beats/minute)
- Tachypnea (respiratory rate [RR] greater than 20 breaths/minute)
- Cutaneous vasoconstriction: cold, clammy, blue, mottled skin (although not typical of distributive shock)
- Abnormal mental status (agitation, confusion, stupor, or coma)
- Oliguria: urine output less than 0.5 mL/kg/hour
- Metabolic acidosis (usually because of an elevated blood lactate level)
- Decreased venous oxygen saturation (mixed [SvO_2], central [$ScvO_2$]) (reflects a mismatch between oxygen supply [$\dot{D}O_2$] and demand [$\dot{V}O_2$])

Not all these described findings are encountered in every patient with shock, and considerable variability exists in both the rapidity and the sequence of onset. This depends on the severity of the initiating event, the underlying mechanism, and the baseline condition of the patient, including medications that may alter the clinical presentation. It is important to consider the patient's medical and pharmacologic history, while monitoring for subtle clinical changes that may signal impending deterioration and necessitate immediate intervention.

TREATMENT OVERVIEW

The treatment of patients in shock requires both treatment of the underlying cause of shock, as well as early, aggressive measures to maintain adequate perfusion to vital organs. The general measures used are the restoration of volume in hypovolemic patients, the use of vasopressors or inotropic agents when volume resuscitation is inadequate to maintain perfusion, and careful monitoring of the hemodynamic status of the patient. In sepsis, specific hemodynamic goals have been determined.[4] In other types of shock, specific goals have not been established; however, the principles of ensuring adequate tissue perfusion are the same.

HEMODYNAMIC MONITORING

Hemodynamic monitoring in critically ill patients is mandatory to properly assess and manage various shock states. Both noninvasive and invasive monitoring techniques can be used to measure cardiovascular performance and differentiate the causes of various conditions that result in hypoperfusion and organ dysfunction. The values obtained with hemodynamic monitoring should always be used in conjunction with clinical judgment.

Noninvasive Monitoring

Noninvasive measures are an important part of hemodynamic monitoring. Clinical examination and vital signs (temperature, HR, blood pressure [BP], RR) provide valuable information regarding the cardiovascular system and organ perfusion. Other noninvasive techniques for monitoring the hemodynamic status of patients include pulse oximetry (for measuring arterial oxygen saturation [SaO_2]) and transthoracic echocardiography, which can estimate the functional status of the heart and heart valves. Cardiac telemetry and/or electrocardiogram may help identify a variety of causes for shock (e.g., arrhythmia, ischemia, pericarditis). Although important, noninvasive measures have limitations, and certain hemodynamic values important for the diagnosis and assessment of illness, as well as the patient's response to therapy, must be measured invasively at the present time.

Invasive Monitoring

ARTERIAL PRESSURE LINE

The arterial line is a common tool in the ICU. It consists of a small catheter placed into an artery (usually the radial or femoral artery) under sterile conditions and attached to a pressure transducer. This allows for continuous measurement of BP and can be more accurate than a sphygmomanometer in patients with shock, cardiac arrhythmias, calcified arteries, or high systemic vascular resistance (SVR). It also provides for easy access for arterial blood gas (ABG) samples to be drawn and analyzed. Arterial lines should never be used for medication administration.

CENTRAL VENOUS CATHETER

Common in the ICU, the central venous catheter consists of a large-bore catheter usually inserted into either a subclavian or a jugular vein. It can be used for infusion of fluid and medications or frequent laboratory studies. When attached to a pressure transducer, it can be used to measure the central venous pressure (CVP), a reflection of right atrial pressure and volume status. In patients with sepsis, however, guidelines call for dynamic rather than static variables (e.g., CVP) to guide fluid resuscitation.[4] Central venous catheters are preferred to peripheral venous access for administration of large fluid volumes, blood products, or vasopressors in patients with shock, but resuscitative efforts should not be delayed if peripheral access is available. Central venous catheters that can continuously measure the central venous oxygen saturation ($ScvO_2$) have been developed and are becoming more common. These catheters allow for the assessment and monitoring of tissue perfusion and the response to interventions. Low $ScvO_2$ has been associated with worse outcomes.[5–7]

PULMONARY ARTERY CATHETER

The introduction of flow-directed, balloon flotation pulmonary artery (PA) catheters by Swan and colleagues[8] (Swan–Ganz catheter) in the 1970s represented a major advance in invasive bedside hemodynamic monitoring. The PA catheter is inserted via a central venous access and positioned into the PA; this enables clinicians to assess both right and left intracardiac pressures, determine CO, and obtain mixed venous blood samples. These capabilities allow one to evaluate volume status and ventricular performance, derive hemodynamic indices, and determine systemic $\dot{D}O_2$ and $\dot{V}O_2$. There are several versions of the PA catheter. Some provide additional lumens for intravenous (IV) infusions, temporary transvenous pacing, and continuous monitoring of Svo_2.[9] Catheters are available that can measure CO on a continuous basis. The essential components for hemodynamic monitoring are incorporated in the standard quadruple-lumen catheter pictured in Figure 17-2. This catheter is composed of multiple lumens, each terminating at different points along the catheter. When properly positioned, the proximal port (C) terminates in the right atrium and is used to measure right atrial pressure, to inject fluid for CO determination, and to administer IV fluids. The distal port (B), which terminates at the tip of the catheter (E), is positioned in the PA beyond the pulmonary valve and is used to measure PA and pulmonary capillary wedge pressure (PCWP; described in the following) and to obtain mixed venous blood samples. Intermittent inflation of the balloon is accomplished by inserting 1.5 mL of air into the balloon inflation valve (D). The thermistor (A) contains a temperature probe and electrical leads that connect to a computer, which calculates CO by the thermodilution technique.

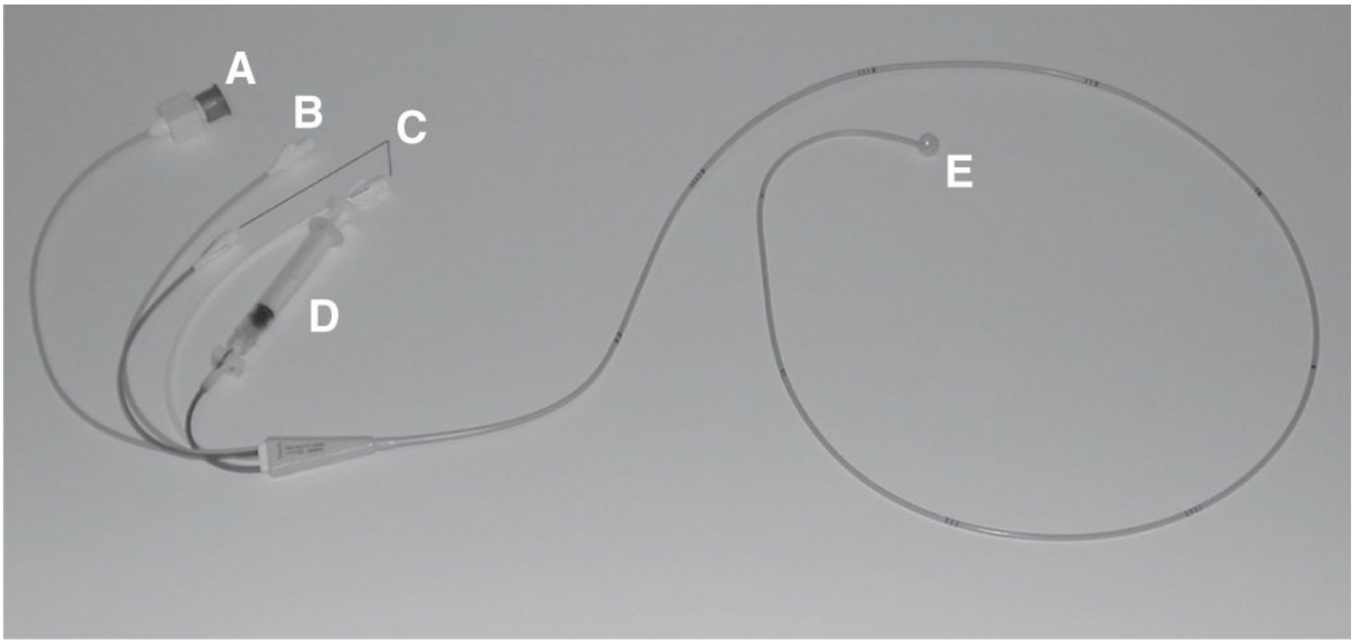


Figure 17-2 Pulmonary artery catheter. See text for definitions of A, B, C, D, and E.

Although the PA catheter is confined to the pulmonary vasculature, left ventricular

(LV) pressure can be ascertained from the PCWP. When the balloon is inflated, the PA catheter becomes lodged or “wedged.” Because forward flow from the right ventricle ceases beyond the wedged PA segment, a static fluid column exists between the LV and the PA catheter tip during diastole when the mitral valve is open. If no pressure gradients are present in the pulmonary vasculature beyond the balloon and if mitral valve function is normal, the PCWP then equilibrates with all distal pressures and thus indirectly reflects left ventricular end-diastolic pressure (LVEDP). Based on the relationship between pressure and volume, the LVEDP is equivalent to the left ventricular end-diastolic volume, or the left-sided preload. Because PCWP measurements are not always available, the diastolic pulmonary artery pressure (DPAP) may provide an estimate of left-sided preload in the absence of pulmonary hypertension or cardiac tamponade.

The use of PA catheters has potential complications. Arrhythmias, thrombotic events, infections, and, very rarely, PA rupture have been reported.[9] Several trials have questioned the routine use of PA catheters. A meta-analysis of 13 randomized, controlled trials found that use of a PA catheter did not have a significant effect on mortality, number of days in the ICU or hospital, or cost.[9] An international consensus conference recommends against the routine placement of the PA catheter in patients with shock.[1] Despite this, the PA catheter can provide essential diagnostic and hemodynamic information for specialists to utilize in certain patient populations. More studies are needed to determine the value of PA catheter data–driven treatment protocols. Because hypotension alone is not required to define shock, the presence of inadequate tissue perfusion on physical examination is more important than the numbers obtained by invasive monitoring.[1] The use of PA catheters has been decreasing in the ICU as newer and less invasive technologies become available. In most situations, the PA catheter is reserved for those patients who specifically require the monitoring of PA pressures and oxygenation parameters, such as patients with pulmonary hypertension, refractory shock, right ventricular (RV) dysfunction, or who are post-cardiac surgery.[1,4]

OTHER MONITORING TOOLS

New technologies to monitor a patient’s perfusion status are being developed. End-tidal carbon dioxide monitors are used to determine $\dot{V}O_2$ and help guide therapies designed to improve $\dot{D}O_2$ and $\dot{V}O_2$. New devices that can measure CO and tissue perfusion noninvasively (or minimally invasively), such as gastric tonometry, esophageal Doppler monitoring, thoracic bioimpedance, and others, have been developed.[10–12] Devices (e.g., PulseCO, PiCCO, LiDCO) that can measure CO by pulse wave analysis are being increasingly used in ICUs as an alternative to the PA catheter.[10–12] An international consensus conference does not currently recommend the newer, less invasive technologies because of lack of validation in patients with shock.[1]

The effective interpretation and management of hemodynamic parameters requires a thorough understanding of the physiologic determinants of CO and arterial pressure. Assuming oxygen content of blood is adequate, CO and SVR are the ultimate determinants of $\dot{D}O_2$, adequate arterial pressure, and tissue perfusion. As outlined in Figure 17-1, CO may be quantified as the product of stroke volume (SV) and HR. SV is determined by preload, afterload, and contractility. Preload is defined as end-diastolic fiber length before contraction and is represented by left ventricular end-diastolic volume (LVEDV). It is approximated by left ventricular end- diastolic pressure (LVEDP) and pulmonary capillary wedge pressure (PCWP). Right ventricular preload is reflected by central venous pressure (CVP) or right atrial pressure (RAP). Afterload is defined as ventricular wall tension developed during contraction. It is determined by the resistance or impedance the ventricle must overcome to eject end-diastolic volume. Left and right ventricular afterload are determined primarily by systemic vascular resistance (SVR) and pulmonary vasular resistance (PVR), respectively. Contractility describes the inotropic state of the myocardium and affects the stroke volume (SV) and cardiac output (CO)independently of preload and afterload. The effects of these factors on hemodynamic parameters are interrelated and complex and must be assessed carefully when selecting therapeutic interventions that will produce the desired response. A review of the determinants of cardiac performance is found in Chapter 14, Heart Failure. Table 17-2 provides definitions of terms and normal hemodynamic indices.

ETIOLOGIC CLASSIFICATION OF SHOCK AND COMMON MECHANISMS

The most common clinical conditions associated with the major forms of shock are reviewed in the subsequent sections and detailed in Table 17-1. Table 17-3 describes the common hemodynamic findings for the various forms of shock.

HYPOVOLEMIC SHOCK

Shock secondary to reduced intravascular volume is referred to as hypovolemic shock. Whether the primary insult is the external loss of fluid (e.g., blood, plasma, or free water) or the internal sequestration of these fluids into body cavities (third spacing), the overall result is reduced venous return or preload (decreased CVP and PCWP) and decreased CO (Table 17-3). The severity of hypovolemic shock depends on the amount and rate of intravascular volume loss and each person’s capacity for compensation. Although responses vary, a healthy person may tolerate an acute loss of as much as 30% of his or her intravascular volume.[13] Compensatory mechanisms such as increased HR, myocardial contractility, and SVR are sufficiently effective for this loss in volume and measurable falls in SBP are not detected. Losses in excess of 40% generally overwhelm compensatory mechanisms, venous return decreases and the patient's condition can deteriorate to overt shock with hypotension and signs of hypoperfusion. If restorative measures are not taken immediately, irreversible shock and death may result. The most common and dramatic cause of hypovolemic shock is hemorrhagic shock in which intravascular volume depletion occurs as a result of bleeding. Trauma is responsible for most cases of acute hemorrhagic shock; other significant causes are listed in Table 17-1.

Table 17-3

Hemodynamic Findings in Various Shock States

	Hypovolemic	Cardiogenic	Distributive (Septic)
Heart rate	↑	↑	↑
Blood pressure[a]	↓	↓	↓
Cardiac output	↓	↓	↑/↓[b]
Preload (PCWP)	↓	↑	↔/↓
Afterload (SVR)	↑	↑	↓

[a] Patients may be in a state of compensated shock in which blood pressure is normal, but clinical signs of hypoperfusion are evident.

[b] Cardiac output is increased early in sepsis but can be decreased in late or severe sepsis.

PCWP, pulmonary capillary wedge pressure; SVR, systemic vascular resistance.

Acute Hemorrhagic Shock

CASE 17-1

QUESTION 1: N.G. is a 64-year-old woman with a history of peptic ulcer disease, who arrives to the emergency department (ED) complaining of diffuse abdominal pain and bright red blood in her stool over the past two days. She is confused and oriented only to person. Her skin is pale and cool, with HR 120 beats/minute, SBP 80 mm Hg, and RR 28 breaths/minute. Describe the physiologic changes in N.G. in response to her gastrointestinal (GI) bleeding. What are the goals of resuscitation in patients with hemorrhagic shock?

N.G. has lost a significant amount of intravascular fluid directly from her GI tract. She is hypotensive with a compensatory increase in both HR and RR. Her pale, cool skin indicates shunting of blood from the periphery to maintain perfusion of vital organs. Based on her clinical presentation, N.G. is in decompensated shock.

The major hemodynamic abnormality in hypovolemic shock is decreased venous return (preload) to the heart, resulting in a decrease in CO. $\dot{D}O_2$ to the tissues is reduced from this and the loss of oxygen-carrying hemoglobin (Hgb). The physiologic response of the body to a sudden decrease in volume (preload) is to activate the hypothalamic–pituitary–adrenal axis and autonomic nervous system to release catecholamines (epinephrine, norepinephrine). The subsequent increase in HR and contractility help maintain CO. The peripheral vasoconstriction caused by the sympathomimetic response helps maintain arterial pressure. In addition, fluid shifts from the interstitial spaces into the vasculature to increase preload. These responses are effective at maintaining BP in patients with a loss of up to approximately 30% of the total blood volume. N.G.'s increased HR and signs of peripheral vasoconstriction are consistent with these compensatory changes. Her SBP is still low, however, and she has signs of decreased perfusion to her brain, manifested by confusion and disorientation. Given the severity of her condition, if intravascular losses are not rapidly replaced, myocardial dysfunction may ensue and lead to irreversible shock.

The goals of resuscitation of patients in hypovolemic shock are the correction of inadequate tissue perfusion and oxygenation, and limiting secondary insults. HR, BP, and urine output have been traditional markers for the adequacy of resuscitation, but reliance on these end points alone is acceptable only in the initial management of hemorrhagic shock. One concern is that patients may persist in a state of compensated shock even after these parameters are normalized.[14] Ongoing deficiencies in $\dot{D}O_2$ to vital organs may progress, and if left untreated, organ dysfunction and death may result. Measurement of base (bicarbonate) deficit and lactate levels can be used to assess the global adequacy of perfusion by tracking trends, ensuring that the levels are decreasing. Metabolic acidosis can signal that resuscitation is incomplete despite normal vital signs.

TREATMENT

Choice of Fluid in Hypovolemic Shock

CASE 17-1, QUESTION 2: Is an IV saline solution adequate to compensate for N.G.'s blood loss? What other fluid options are available to resuscitate this patient?

Once an adequate airway is established and initial vital signs are obtained, the most important therapeutic intervention in hypovolemic shock is the infusion of IV fluids. Initially, crystalloids or colloids are used to restore blood volume as blood products are limited, costly, and transfusion of these products carries a risk.[15] Blood products may not be immediately available and are frequently unnecessary to manage mild shock (less than 20% blood loss).

Crystalloids Versus Colloids

Resuscitative crystalloids are isotonic solutions that contain either saline (0.9% sodium chloride; "normal saline" [NS]) or a saline equivalent (lactated Ringer's

[LR] solution) (Table 17-4) . Colloidal solutions contain high molecular weight molecules that are derived from natural products, such as proteins (albumin), carbohydrates (dextrans, starches), and animal collagen (gelatin), and largely remain in the intravascular space, thereby contributing to colloid oncotic pressure (COP) (Table 17-5). Healthy semipermeable capillary membranes are relatively impermeable to these large molecules.

The choice of a crystalloid versus a colloid solution to restore blood volume in hemorrhagic shock is controversial. The controversy primarily involves the ultimate distribution of these fluids in the extracellular compartment, which, in turn, depends on their composition. Isotonic solutions (NS or LR) freely distribute within the extracellular fluid compartment, which is divided between the interstitial and intravascular spaces at a ratio of 3:1. This distribution is determined by the net forces of COP and hydrostatic pressure, both inside and outside the capillary vascular space. Consequently, large volumes of crystalloid fluid are required to expand the intravascular space during resuscitation. In contrast, intact capillary membranes are relatively impermeable to colloids and, therefore, colloids effectively expand the intravascular space with little interstitial loss. Comparatively smaller volumes of colloids than of crystalloids are required for resuscitation, and their duration of action is longer. It is thought that 3 to 4 times as much volume of crystalloid compared to colloid is necessary to provide the same degree of volume expansion.

Table 17-4

Composition and Properties of Crystalloids

Solution	Sodium (mEq/L)	Chloride (mEq/L)	Potassium (mEq/L)	Calcium (mEq/L)	Magnesium (mEq/L)	Lactate (mEq/L)	Tonicity Relative to Plasma	Osmolarity (mOsm/L)
5% Dextrose	0	0	0	0	0	0	Hypotonic	253
0.9% Sodium chloride	154	154	0	0	0	0	Isotonic	308
Plasma-Lyte (Baxter)	140	103	10	5	3	8	Isotonic	312
Lactated Ringer's	130	109	4	3	0	28	Isotonic	273
7.5% Sodium chloride	1,283	1,283	0	0	0	0	Hypertonic	2,567

Table 17-5

Composition and Properties of Colloids

Solution	Colloid Type	MWw (KDaltons)	DS	Sodium (mEq/L)	Chloride (mEq/L)	Potassium (mEq/L)	Calcium (mEq/L)	Glucose (mg/L)	Osmolar (mOsm/
Albumin	Blood-derived	67		130–160		≤2			300
Hespan 6%	Hetastarch	450	0.7	154	154				309
Hextend 6%[a]	Hetastarch	450	0.7	143	124	3	5	90	307
Voluven	Tetrastarch	130	0.4	154	154				308
Gentran 40	Dextran 40	40		154	154			50	308
Gentran 70	Dextran 70	70		154	154			50	308

[a] Hextend also contains magnesium 0.9 mEq/L and lactate 28 mEq/L

MWw, weight-averaged molecular weight (number of molecules at each weight multiplied by the particle weight divided by the total weight of all the molecules); MWn, arithmetic mean of all particle molecular weight; DS, proportion of substituted to non-substituted glucose moieties (higher DS is more resistant to hydrolysis)

Proponents of crystalloids argue that both intravascular and interstitial fluids are depleted in hypovolemic shock because of the rapid shifts between the extracellular compartments. Volume replacement of both fluid spaces is best accomplished by using crystalloids. In addition, loss of capillary integrity in shock can cause the leak of larger molecules (including colloidal molecules) into the interstitium. This increase in the interstitial oncotic pressure would favor fluid movement out of the vascular space into the tissues, with resultant edema. Crystalloids do not produce allergic or hypersensitivity reactions like many of the colloidal agents. Colloids can also cause coagulopathies, have been associated with an increased incidence of acute kidney injury, and are much more expensive than crystalloids.

Proponents of colloids maintain that resuscitation with these solutions more rapidly and effectively restores intravascular volume after acute hemorrhage. For a given infusion volume, colloidal solutions (e.g., albumin) will expand the intravascular space 2 to 4 times more than crystalloids, and the intravascular effects persist longer. Traditionally, it has been contended that the larger volumes of crystalloids necessary to restore the vascular space will further dilute the plasma proteins, resulting in a decreased COP and promotion of pulmonary edema. However, clinical studies comparing colloids with crystalloids have failed to show any differences in the development of pulmonary edema. This is likely because of the relatively high alveolar capillary permeability to albumin causing a decreased transcapillary COP gradient. Research suggests that certain subgroups may be at greater risk for the development of pulmonary edema, but considerable variance remains because of differences in physiologic end points, criteria for assessing pulmonary edema, and the extent of shock.

Numerous meta-analyses have compared resuscitation with crystalloids or colloids in an effort to find a consensus among divergent clinical trial results. Two recent meta-analyses failed to show a mortality benefit for resuscitation with colloids compared to crystalloids in patients with sepsis, trauma, burns, or following surgery.[16,17] Patients receiving hydroxyethyl starch were at an increased risk of death and acute kidney injury. It is important to recognize that study inclusion criteria (heterogeneity), differences in fluid management, and dosages provide several limitations to these meta-analyses. Conversely, a more recent randomized, controlled trial found no difference in 28-day mortality or the need for renal replacement therapy in patients with hypovolemic shock who received crystalloid- or colloid-based resuscitation.[18] Any mortality difference between colloids and crystalloids at 90 days remains uncertain as trials have shown conflicting results.[18–21]

A Cochrane Database meta-analysis found that volume resuscitation with albumin in hypovolemic critically ill patients did not reduce mortality compared to crystalloids and was possibly associated with an increased risk of death in patients with burns or hypoproteinemia.[22] This meta-analysis was heavily influenced by the SAFE trial, the largest randomized, prospective trial to evaluate albumin versus NS solution resuscitation in the critically ill.[23] The primary end point of the SAFE trial was 28-day mortality, which showed no difference between albumin and NS solution. No statistical differences were identified in any of the predetermined subgroups (trauma, adult respiratory distress syndrome [ARDS], severe sepsis). A trend toward increased mortality in the trauma patients who received albumin led to a post hoc follow-up study in patients who had traumatic brain injury.[24] A higher mortality rate was seen in patients with severe traumatic brain injury (Glasgow Coma Scale 3–8), who received albumin versus those receiving saline for fluid resuscitation.

More certain differences between colloids and crystalloids are availability and cost. Crystalloid solutions are readily available and remain 20 to 100 times cheaper than colloidal solutions; therefore, treatment costs can be significantly different and must be considered when choosing between therapies with similar outcomes.[25] Given the lack of evidence for a significant clinical difference between crystalloids and colloids and the greater expense of using albumin, the guidelines for the use of resuscitation fluids developed by the University Hospital Consortium, a nonprofit alliance of US academic medical centers, remain unchanged.[26] Use of either NS or LR solution would be appropriate for N.G. Colloidal products are not needed at this time; instead, they should be reserved for persistent hypotension despite an appropriate crystalloid challenge.[26] Given the severity of N.G.'s hemorrhagic shock, blood transfusion is indicated and should be transfused as soon as available.[15]

Crystalloids

CASE 17-1, QUESTION 3: A large-bore IV catheter is inserted into N.G.'s arm and STAT blood samples are sent for type and cross-match, complete blood count (CBC), prothrombin time (PT), partial thromboplastin time (PTT), and serum chemistry (blood urea nitrogen [BUN], creatinine [SCr], Na, K, Cl, and bicarbonate). Warmed LR solution (2 L) is infused rapidly, and the GI endoscopy suite is notified. N.G.'s SBP has increased to 94 mm Hg, but the bleeding has not stopped. A Foley catheter is inserted to measure urine output. LR is continued, with 500- to 1,000-mL boluses ordered to maintain hemodynamic stability while waiting for fully cross-matched blood. Are the doses of LR given to N.G. appropriate? What clinical and objective parameters should be monitored to determine the success of fluid replacement?

Volume Requirements

Isotonic crystalloids equilibrate rapidly between the interstitial and the intravascular spaces at a ratio of 3:1. For every liter of fluid infused, approximately 750 mL will pass into the interstitium, whereas 250 mL will remain in the plasma. Based on estimated blood loss, the "three-to-one rule" may be applied as a general guideline: for each 1 mL of blood loss, 3 mL of crystalloid is infused. Because this determination of blood loss is based solely on clinical assessment and not on quantitative measurements, treatment is best directed by the response to initial therapy rather than the initial classification. Close observation of hemodynamic status with consideration of the patient's age, particular injury, and pre-hospital fluid therapy is essential to avoid inadequate or excessive fluid administration.

A safe and effective resuscitative approach for crystalloids in hemorrhagic shock is to give 2 L of fluid as an initial bolus as rapidly as possible for an adult or 20 mL/kg for a pediatric patient.[13] Additional fluid boluses may be necessary, depending on the patient's response. Between boluses, fluids are slowed to maintenance rates (150–200 mL/hour for adults, weight-based up to 100 mL/hour for children[27]), with ongoing evaluation of the patient's physiologic response for signs of continued blood loss or inadequate perfusion that would indicate the need for additional volume replacement. The fluid boluses given to N.G. are an appropriate initial measure, then assessment of her perfusion is vital to determine the need for additional boluses.

Normalization of BP, HR, and pulse pressure (difference between SBP and diastolic blood pressure [DBP]) indicate improved circulation. Signs that actual organ perfusion is normalizing and that fluid resuscitation is adequate include improvements in mental status, warmth and color of skin, improved acid–base balance, and increased urinary output. The minimal acceptable urine output is 0.5 mL/kg/hour for an adult, 1 mL/kg/hour for a child, and 2 mL/kg/hour in an infant under 1 year of age.[13] Persistent metabolic acidosis in normothermic shock usually indicates the need for additional fluid resuscitation; sodium bicarbonate administration is controversial but is not recommended unless the pH is less than 7.2.[14] Monitoring serum lactate and base deficit is important to determine adequate resuscitation. As perfusion improves, lactate and base deficit will decrease; thus, the actual values are not as important as the trend. It is important to note that resuscitation is not defined by just one value or number, such as BP, but by the constellation of indicators of overall perfusion.

Lactated Ringer's Versus Normal Saline

CASE 17-1, QUESTION 4: Is there an advantage to using LR solution versus NS solution?

The choice of replacement fluid varies widely in clinical practice. Normal saline solution has a supraphysiologic chloride content, while LR contains a more balanced chemical composition (Table 17-4). Large volumes of NS can cause hyperchloremic metabolic acidosis, thereby worsening the tissue acidosis from hypovolemic shock. This may also cause immune and renal dysfunction, but survival differences have not been seen and the clinical significance is unknown.[28,29] LR, in contrast, is a buffered solution designed to simulate the intravascular plasma electrolyte concentration. It contains 28 mEq/L of lactate, which is metabolized to bicarbonate in patients with normal circulation and liver function. In situations in which hepatic perfusion is reduced (20% of normal) or hepatocellular damage is present, lactate clearance may be significantly decreased, particularly in combination with hypoxia (SaO_2 50% of normal).[30] In patients with shock and those having cardiopulmonary bypass during surgery, the half-life of lactate, normally 20 minutes, increases to 4 to 6 hours and 8 hours, respectively. Because unmetabolized lactate can be converted to lactic acid, prolonged infusion of LR could cause tissue acidosis in predisposed patients. Concern about the high sodium and chloride content in NS has led to the first-line selection of more balanced resuscitative solutions (e.g., LR) in patients at high risk of acidosis, including those with trauma, burns, diabetic ketoacidosis, or undergoing surgery.[28] LR, however, should be avoided in patients with metabolic alkalosis, lactic acidosis, or hyperkalemia. In practice, NS and LR solutions typically are used interchangeably because neither solution appears to be superior to the other.

Hypertonic Saline

CASE 17-1, QUESTION 5: What is the role of hypertonic saline (HS) solution in the setting of hemorrhagic shock?

The advantage of HS (3% to 7.5% NaCl) solution as a resuscitative fluid is the smaller volume of fluid required to expand the intravascular compartment compared with isotonic solutions. This could be a particular advantage in the pre-hospital setting (e.g., field rescue by emergency medical technicians) given the large volumes of fluids necessary to restore ongoing blood loss.

With a high concentration of sodium, HS solution exerts an osmotic effect, translocating fluid from the interstitial and intracellular compartments to the intravascular space. Consequently, plasma volume is rapidly expanded to a greater extent than similar volumes of crystalloid solutions, and systemic BP, CO, and $\dot{D}O_2$ are readily increased. HS solution also improves myocardial contractility, causes peripheral vasodilation, and redistributes blood flow preferentially to the splanchnic and renal circulations. In addition, intracranial pressure is reduced, but to date HS has not been shown to improve outcomes in trauma patients with concomitant head injury.[31] Other recent studies have shown that HS may have beneficial effects on circulation, inflammation, and endothelial function, which may be beneficial in patients with septic shock and acute lung injury.[31,32] More robust clinical trials are needed to determine if these preliminary findings translate into improved clinical outcomes.

It is difficult to make conclusions about the utility of HS for fluid resuscitation because of the heterogeneity of studies and solutions. The majority of data regarding the use of HS in hypovolemic shock come from the trauma population. No high-quality trials are available in patients with GI bleeding. HS effectively raises BP in patients with hypovolemic shock, but as with isotonic saline the effects are transient and it has not been shown to improve mortality.[33]

These clinical trials suggest that HS solution may be safe and effective for the initial resuscitation of hemorrhagic shock. Despite these positive findings, HS solutions are not widely used. This is possibly because of its safety profile as a high-risk medication. HS is prone to dosing and administration errors, particularly when used by clinicians who are unfamiliar with the product. The osmolarity of HS can range from 1,026 to 2,567 mOsm/L (3%–7.5% NaCl), so infusion through a central line is preferred to minimize phlebitis. HS may cause hypernatremia and hyperchloremic metabolic acidosis, resulting in rapid fluid shifts between cellular compartments and potentially devastating effects such as osmotic demyelination syndrome. However, most studies have not reported such events, which may be because of a lack of power or the relatively small volumes of HS used for resuscitation.

Blood Replacement

CASE 17-1, QUESTION 6: N.G. has received 4 L of LR solution to maintain hemodynamic stability. Her current vital signs are BP 98/54 mm Hg, HR 108 beats/minute, and RR 30 breaths/minute. She is still confused and is becoming more agitated and combative. Urine

---

output has been only 30 mL in the past 30 minutes. Laboratory results include the following:

Hematocrit (Hct), 21% (down from 26%)
Hemoglobin (Hgb), 7.1 g/dL (down from 8.9 g/dL)
pH, 7.14
PCO_2, 34 mm Hg

PO_2, 106 mm Hg

HCO_3^-, 16 mEq/L

Two units of packed red blood cells (PRBCs) are now available, and N.G. is being prepared for the GI endoscopy suite. Describe the current status of N.G.'s resuscitation and the need for blood products.

N.G. is still exhibiting signs of inadequate tissue perfusion. Although her BP has improved and her HR has decreased, her mental status has declined, she is oliguric, and her ABG indicates metabolic acidosis. N.G. has not been adequately resuscitated from her hemorrhage, is still actively bleeding, and should receive available blood at this point.

The prior conventional approach to the transfusion of critically ill patients was to maintain the hemoglobin greater than 10 g/dL or the hematocrit greater than 30%. It has been argued that these liberal transfusion goals are justified in acutely ill patients, particularly those with cardiovascular disease, because the compensatory mechanisms to maintain tissue $\dot{D}O_2$ are impaired. However, randomized, controlled trials have shown that a restrictive transfusion strategy (target hemoglobin 7 to 8 g/dL or transfused if symptomatic) is associated with equivalent or better outcomes in hemodynamically stable critical care, surgical, and medical patients.[34]

In acute hemorrhage, the actual degree of blood loss is not accurately reflected by the hemoglobin and hematocrit values, and it also does not take into account the body's ability to compensate for the loss of oxygen-carrying capacity. Because it takes at least 24 hours for all fluid compartments to come to equilibrium, a normal hematocrit (or hemoglobin concentration) in the setting of hemorrhagic shock does not rule out significant blood loss or indicate adequacy of transfusion. Only when equilibrium has been reached can these measures be used reliably to gauge blood loss. On the other hand, if cardiopulmonary function is normal and volume status is maintained, an increase in CO can compensate for a reduction in hemoglobin (O_2 content) to a certain degree (Fig. 17-1).

Because inadequacy of tissue perfusion, and hence $\dot{D}O_2$, is the primary abnormality in shock, the need for transfusion therapy is more accurately determined by the patient's symptoms and oxygen demand, rather than an arbitrary hematocrit or hemoglobin value.[15] Calculation of $\dot{D}O_2$ and $\dot{V}O_2$ can be used to determine the adequacy of perfusion. Although these values can be determined by use of a PA catheter and arterial and venous blood samples, for practical purposes the patient's response to initial fluid resuscitation and clinical signs of inadequate tissue perfusion are the primary determinants for blood transfusion. Patients who are not acutely bleeding and who do not respond to initial volume resuscitation or who transiently respond but remain tachycardic, tachypneic, and oliguric clearly are underperfused and will likely require blood transfusion. Patients who have acute bleeding or who demonstrate signs of underperfusion should be considered for transfusion much sooner; thus, N.G. should receive a transfusion.

Adverse Effects of Transfusion

CASE 17-1, QUESTION 7: After the transfusion, N.G. has a serum potassium concentration of 4.7 mEq/L compared with 4.2 mEq/L before the transfusion. Could this be a result of the blood product? What other potential acute transfusion-related complications are associated with PRBC administration?

Possible risks of blood transfusions include febrile and allergic reactions, hemolytic reactions, electrolyte abnormalities, infectious disease transmission, coagulopathies, and immunosuppression.[35] Febrile non-hemolytic and allergic transfusion reactions are the most common adverse reactions. Transfusions can also cause acute lung injury from activation of recipient neutrophils, which cause capillary endothelial damage. Transfusion-associated circulatory overload results in pulmonary edema in patients with limited cardiac reserve (elderly, infant, renal failure, heart failure) or after massive transfusions. Recognition of donor-recipient ABO incompatibility and the signs and symptoms of a transfusion reaction (e.g., anxiety, infusion site pain, chills, rigors, fever, hypotension, tachycardia, hemolysis, hemoglobinuria) can prevent unnecessary morbidity and mortality by stopping the infusion and providing supportive therapy.

Hemolytic transfusion reactions are the most common cause of fatalities from blood transfusions; however, it is unlikely that N.G. is having a true hemolytic reaction. Banked blood is stored with a citrate anticoagulant additive. With multiple transfusions, the large amount of citrate can cause hypocalcemia and acid–base abnormalities. Hyperkalemia also can occur because transfusion of stored blood causes the release of potassium from hemolyzed (ruptured) red blood cells. The increase in serum potassium observed in N.G. may be from the blood product; although, the average amount of extracellular potassium ranges from less than 0.5 to 7 mEq/unit of blood, so the transfusion is unlikely the culprit. The increased potassium may simply reflect hemolysis of blood cells in the test tube after the blood draw. In either case, the measured serum concentration of 4.7 mEq/L is not sufficiently high to warrant immediate treatment but should be monitored.

Blood products and donors are screened for disease; thus, transmission of bacterial or viral illness is rare. It is estimated that the transmission of hepatitis C is 1:1,149,000, and human immunodeficiency virus is 1:1,467,000.[36] Protozoan infection and prion disease are also transmissible through infusion but are an even lower risk. Hemostatic abnormalities, specifically coagulopathies and thrombocytopenia, may be transiently related to dilution from administration of large volumes of crystalloids, colloids, or banked blood, but they are more likely caused by the extent of injury and the development of disseminated intravascular coagulopathy (DIC). Banked whole blood is usually reserved for massive transfusions and contains sufficient coagulation factors (including labile factors V and VIII) to maintain hemostasis during the life span of the unit; however, it does not contain platelets because they do not survive the temperatures required for red blood cell storage.

Immunosuppression has also been associated with blood transfusions as evidenced by enhanced graft survival in renal transplant recipients, tumor recurrence in patients with colorectal carcinoma, and postoperative infections. Transfusion-related immunosuppression is multifactorial, but it is most likely caused by the infusion of donor white blood cells (WBCs), which creates a competition between the donor and the recipient leukocytes. Transfusion-related immunomodulation can be limited by leukoreducing PRBCs prior to transfusion. The majority of blood in the United States is leukoreduced, but it is not a universal practice primarily because of cost. Patients who are immunosuppressed, undergoing cardiac surgery, or receiving chronic transfusions should receive leukoreduced blood. This mechanism is not, however, the only cause because immunosuppression is associated with autologous blood transfusions as well as the infusion of plasma alone.

Because of the limited supply and potential adverse effects associated with blood, research is ongoing to develop blood substitutes. The ideal agent would have a longer shelf life, a reduced risk of disease transmission, and less risk of transfusion reactions. The agents in various stages of clinical research include the modified hemoglobins and the perfluorocarbons.[37] Problems have occurred with some of the products thus far, such as short half-life, vasoconstriction, GI disturbances, and flu-like symptoms. The exact role the blood substitutes would play in transfusions is unclear. No agents are approved, but research is continuing.

Postoperative Hypovolemia

HYPOVOLEMIA VERSUS PUMP FAILURE

CASE 17-2

QUESTION 1: P.T. is a 58-year-old man who arrives to the ED via ambulance after a motor vehicle accident. He has remained conscious during the event, but his mental status fluctuates between somnolent and agitated with a Glasgow Coma Scale of 10 (moderate injury). Chest CT reveals a type II proximal descending thoracic aortic injury. P.T. is taken for an emergent surgical repair of his aorta. He has been admitted to the ICU after surgery and is intubated and receiving 60% oxygen. His ABGs are adequate, and he is receiving 150 mL/hour of LR solution IV. His initial postoperative and 2-hour postoperative hemodynamic profiles are as follows (initial parameters in parentheses):

BP (S/D/MAP), 86/44/58 mm Hg (100/52/68 mm Hg)
HR, 96 beats/minute (88 beats/minute)
CO, 3.2 L/minute (4.8 L/minute)
CI, 1.9 L/minute/m^2 (3.3 L/minute/m^2)
CVP, 6 mm Hg (12 mm Hg)
PA pressure (S/D), 18/8 mm Hg (24/14 mm Hg)
PCWP, 13 mm Hg (18 mm Hg)
SVR, 1,080 $\text{dyne}\cdot\text{s}\cdot\text{cm}^{-5}$ (1,560 $\text{dyne}\cdot\text{s}\cdot\text{cm}^{-5}$)

Urine output, 0.4 mL/kg/hour (1.2 mL/kg/hour)
Temperature, 37.4°C (34.8°C)
Hct, 32% (31%)

From the hemodynamic profile, determine whether P.T. is hypovolemic or experiencing pump failure after his surgery.

Most of P.T.'s hemodynamic changes are consistent with hypovolemia. These include a drop in BP, CVP, PA pressure (PAP), PCWP, CO, and urine output. The decrease in CVP and PCWP suggest that preload is reduced, resulting in a lower CO. The pulse pressure is narrowed, suggesting either blood flow or ventricular contractility has decreased. (Decreases in pulse pressure correlate with decreases in SV or left ventricular stroke work index [LVSWI]). P.T.'s HR increased slightly, but it is unclear whether he was taking any medications, such as a β-blocker, before his injury. As body temperature rises postoperatively, vasodilation decreases SVR and increases the intravascular space. If intravascular volume is inadequate and increased sympathetic tone cannot generate a sufficient CO, mean BP falls. The decline in urine output reflects a compensatory drop in renal perfusion. The most likely explanation for the hemodynamic change in P.T. is hypovolemia. The PCWP would be higher if P.T. was in cardiogenic shock; although he also should be evaluated for the occurrence of a perioperative cardiac event (myocardial infarct). His ABG should be checked to assess oxygen requirements.

CAUSES

CASE 17-2, QUESTION 2: What are the most likely causes of hypovolemia in P.T.?

Common causes of hypovolemia in surgical patients are postoperative bleeding, third spacing, and temperature-related vasodilation. Postoperative bleeding can produce hypovolemia; however, P.T.'s initial and 2-hour postoperative Hct of 31% and 32%, respectively, do not support bleeding as a cause.

After major vascular or bowel surgery and in cases of burns or peritonitis, patients have an internal redistribution of fluids, called third spacing, which can result in intravascular volume depletion. It is not unusual for patients to third-space significant amounts of intravascular volume. The interstitial space and bowel walls can sequester large amounts of fluid, and this can produce a state of relative hypovolemia as is occurring with P.T. This is likely in the first 12 to 24 hours after the surgical procedure. P.T. is receiving 150 mL/hour of LR solution, but this is apparently not sufficient to maintain his intravascular volume.

Mild hypothermia is common during operative procedures. Vasodilation occurs as patients warm postoperatively, expanding the intravascular space. If the amounts of IV fluids administered are insufficient to compensate for the increased venous capacitance, BP and CO will decline during the rewarming phase, which can range from 1 to 6 hours. P.T. has rewarmed from 34.8°C to 37.4°C in 2 hours, which is not unusual after a major operative procedure. His temperature could conceivably rise to as high as 38°C to 38.5°C during the first 12 to 24 hours after surgery.

Other considerations include inadequate fluid administration during the operative procedure and the effects of drugs given in the operating room or in the immediate postoperative period (e.g., opioids, sedatives, inhaled anesthetics) that cause systemic vasodilation.

VOLUME REPLACEMENT AND VENTRICULAR FUNCTION

CASE 17-2, QUESTION 3: How will volume replacement improve P.T.'s CO and perfusion pressure?

The Frank–Starling mechanism indicates that the volume of blood returned to the heart is the main determinant of volume pumped by the heart. Therefore, as venous return is increased, the CO also will increase within physiologic limits until the optimal preload is achieved at which point further volume has minimal effect on SV (Fig. 17-1). The PCWP, the best indicator of LV preload, and the CVP, a marker of RV preload and overall estimate of volume status, are low because of declining venous return in P.T.

A ventricular function curve can be constructed by plotting a measure of cardiac pumping (CO, SV, or LVSWI) against a measure of preload (Fig. 17-3). Two hours after surgery, P.T.'s CVP has fallen from 12 to 6 mm Hg and his CO has fallen from 4.8 to 3.2 L/minute. Therefore, additional volume replacement is warranted.

CASE 17-2, QUESTION 4: P.T. is given a 500-mL bolus of NS solution in 10 minutes, and this results in the following hemodynamic profile:

BP (S/D/M), 96/54/68 mm Hg
HR, 88 beats/minute
CO, 3.9 L/minute
Cardiac Index (CI), 2.4 L/minute/m^2
CVP, 10 mm Hg
PCWP, 15 mm Hg

Assess P.T.'s response to the fluid challenge (see Table 17-2 for normal values).

According to the Frank–Starling curve, a small change in preload in response to a volume challenge with a minimal change in CO represents a ventricle on the flat portion of the ventricular function curve (Fig. 17-3). Additional fluid therapy given to these patients can increase their risk for pulmonary edema without improving CO. In contrast, a large change in preload in response to a fluid challenge with a significant increase in CO represents a ventricle on the steep portion of the curve. In P.T., the PCWP indicates he does not have pulmonary edema and the change in CVP from 6 to 10 mm Hg along with the increase in CO show that he is still responsive to fluid. Thus, it is reasonable to administer more fluid to enhance CO and renal perfusion.

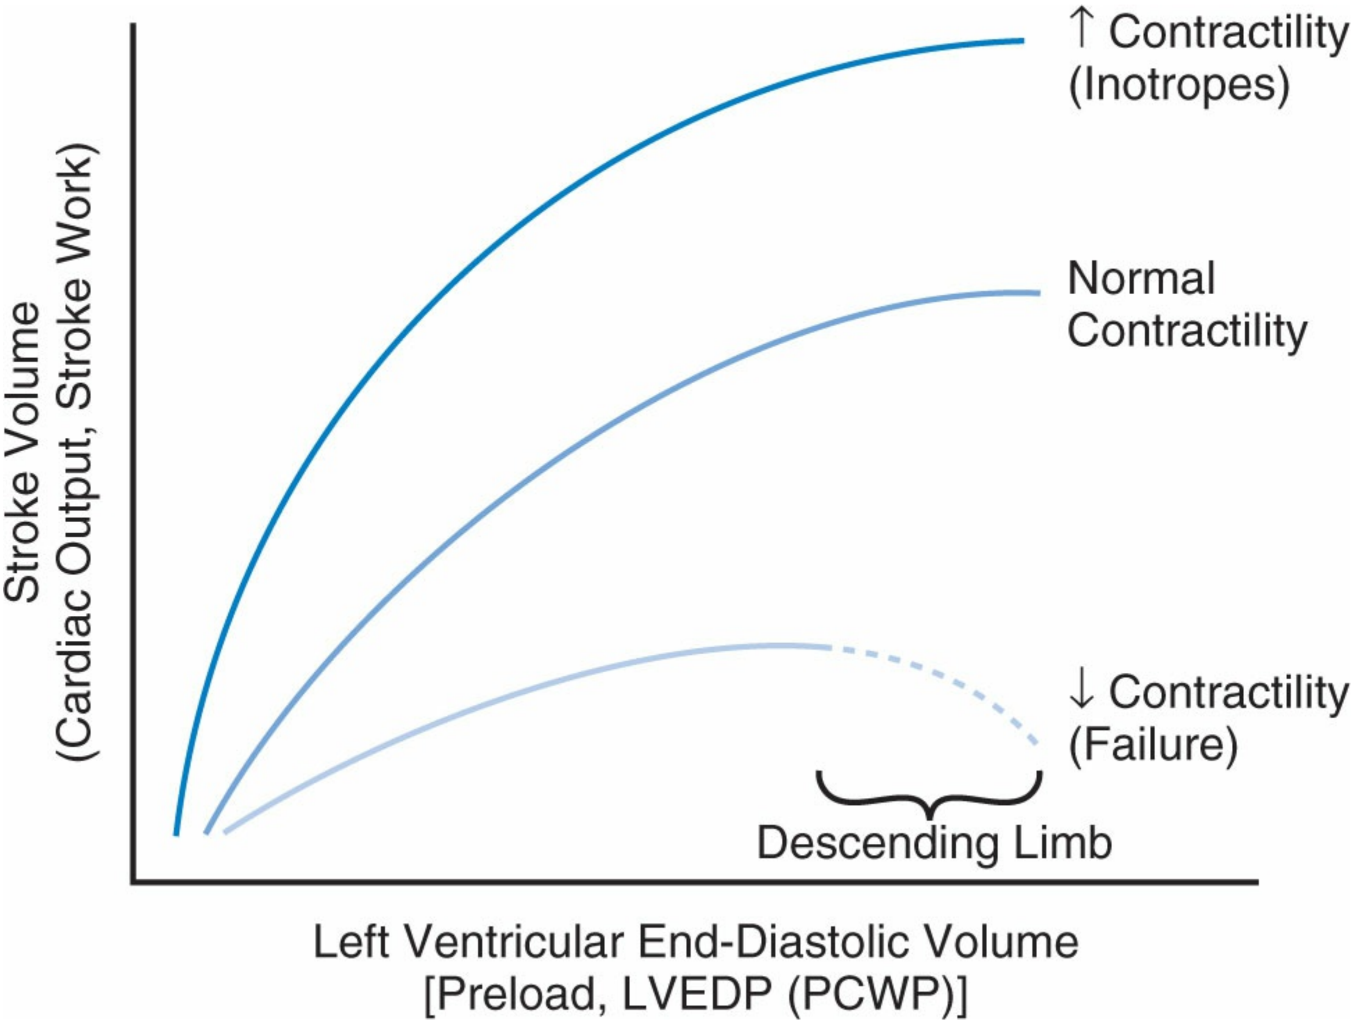

Figure 17-3 Ventricular function (Frank–Starling) curve. In the normal heart, as preload (left ventricular end-diastolic pressure [LVEDP]), measured clinically by pulmonary capillary wedge pressure (PCWP), increases, stroke volume (cardiac output, stroke work) increases until the contractile fibers reach their capacity, at which point the curve flattens. A change in contractility or afterload causes the heart to perform on a different curve. If the contractile fibers exceed their capacity, as with severe heart failure, the heart will operate on the descending limb of the curve.

FLUID CHALLENGE

CASE 17-2, QUESTION 5: One hour after the 500-mL NS bolus, P.T.'s hemodynamic profile returns to his postoperative state. ABGs are acceptable, and LR solution is infusing at 200 mL/hour. P.T. is continuing to "third-space" intravascular volume. Based on this information, develop a strategy for additional fluid challenges in P.T.

Acceptable strategies for administering additional fluid challenges to hypovolemic patients are based on the direction and degree of change in the various hemodynamic parameters in response to a fluid load rather than to their absolute values. CVP has a poor correlation with RV end-diastolic volume because it can be affected by changes in intrathoracic pressure, venous tone, and ventricular compliance (distensibility of the relaxed ventricle or stiffness of the myocardial wall).[38] PCWP and pulse pressure variation are more predictable markers of fluid status. Left ventricular SV (and thus pulse pressure) is inversely related to intrathoracic pressures during respiration; SV is maximally affected at lower filling pressures when the ventricles are operating on the steepest portion of the Frank–Starling curve. A SV that varies at least 12% during a respiratory cycle (between end inspiration and expiration) is highly predictive of a positive response to fluid challenge.[38]

Some practitioners argue that CVP is still an acceptable gauge of fluid responsiveness when used in conjunction with other parameters, including CO, BP, urine output, and tissue perfusion. Using CVP as a guide, an increase in the CVP of 5 mm Hg after a 250- to 500-mL fluid challenge in 10 minutes implies the LV is still functioning on the steep portion of the volume–pressure curve. If the CVP rises abruptly as fluid is given, with a small change in CO, the flat portion of the ventricular function curve has been reached and the IV infusion rate should be slowed. If signs and symptoms of inadequate tissue perfusion worsen or fail to improve and if the CVP remains greater than 10 to 14 mm Hg, fluid challenges should be stopped and inotropic therapy initiated.

Most critically ill patients require a CI above 2.5 L/minute/m^2 and a PCWP of 12 to 18 mm Hg, or a CVP of 8 to 14 mm Hg to maintain an acceptable MAP of 65 to 75 mm Hg. A downward trend in the lactate and base deficit and the change in hemodynamic parameters as well as vital signs and urine output should serve as indicators for whether additional fluid is required.

COLLOIDS

CASE 17-2, QUESTION 6: P.T. has received a total of 3.5 L of NS boluses during the past 6 hours and remains hemodynamically unchanged. His urine output has averaged 0.3 mL/kg/hour for the past 4 hours, indicating volume replacement is inadequate. Given his age and the lack of response to initial crystalloid administration, the decision is made to infuse a colloid solution. How do the colloids compare as a volume expander for P.T., and which agent should be used?

Albumin, the predominant protein in the plasma, accounts for approximately 80% of the COP, the force that maintains fluid in the intravascular space.[39] Human serum albumin is the colloidal agent against which all others are compared for volume-expanding properties. It is commercially prepared from pooled donor plasma that is heat-treated to eliminate the potential for disease transmission. Albumin 5% solution increases plasma volume by approximately 80% to 100% of the volume infused, with an initial duration of action of 16 hours.[39] At steady state (3–5 days), approximately 40% of albumin remains in the intravascular compartment while the rest is in the interstitial compartment. Side effects involve transient clotting abnormalities and anaphylactic reactions (0.5%), both of which are rare.[40] The anaphylactoid reaction is caused by the pasteurization process, causing albumin to polymerize, which produces an antigenic macromolecule. Albumin solutions also contain citrate, which can lower serum calcium concentrations and theoretically lead to decreased LV function. The effects on coagulation and serum calcium are possibly related to the volume of fluid infused rather than albumin administration.[39] Albumin is available as a 5% solution that is iso-oncotic with the plasma and as a 25% solution that is hyperoncotic. The 5% solution is generally preferred for routine volume expansion, whereas the 25% solution is most useful in correcting hypoproteinemia or intravascular hypovolemia in patients with excess interstitial water. Albumin is subject to availability, as approximately 1 L of pooled donor plasma is required to produce 20 to 25 g of albumin.

Hydroxyethyl starch (HES) is a synthetic colloid made from amylopectin, which closely resembles human serum albumin but is less expensive. Available as a 6% solution, HES expands the plasma volume by an amount greater than the volume infused because the high oncotic pressure draws water from the interstitial spaces. HES solutions have varying locations and degrees of substitutions on the glucose molecules, which slow enzymatic degradation and confer greater hydrolysis resistance (Table 17-5). HES solutions have complex pharmacokinetics because of their wide range of molecular weights; with an average molecular weight of 69,000 Da and a range of 1,000 to 3,000,000 Da. Numerous clinical studies have compared albumin and hetastarch for fluid resuscitation in patients with and without shock. However, most of these trials were underpowered and there were no significant differences in mortality.[41,42] Although HES has comparable efficacy to albumin, controversy exists regarding the use of HES owing to adverse effects seen with its use. These adverse effects include severe pruritus, coagulopathy, and renal dysfunction and appear to be class-related effects because the newer lower molecular weight and substitution products are similar.[20,21,43]

Dose-related reductions in platelet count and transient increases in PT, and PTT have been reported with moderate infusions of HES (up to 1,500 mL/day), and coagulopathies persist for up to 7 days with larger volumes.[21,42] HES causes factor VIII and von Willebrand factor levels to be lowered beyond that which can be attributed to hemodilution and also increases fibrinolysis.[42] This places patients with von Willebrand disease at greater risk of bleeding. In critically ill patients, particularly those with sepsis, HES is also associated with a dose-related increased risk of acute kidney injury and greater probability of needing renal replacement therapy.[20,21,44–46] HES now includes warnings of excessive bleeding when used in patients undergoing cardiopulmonary bypass as well as a boxed warning that states these products are contraindicated in critically ill patients. Experts argue that HES should not be used because of the potential adverse effects and that other alternatives are available.

Dextrans are colloidal solutions that are synthesized by bacteria from sucrose and are available in 40,000 and 70,000 Da average molecular weight solutions. These products lack adequately powered randomized trials to adequately examine their efficacy or safety.[42] Like HES, dextrans can cause renal dysfunction, bleeding, and anaphylactic reactions. Dextrans can cause acute kidney injury, possibly because of accumulation of dextran molecules within the renal tubules. They increase bleeding by causing dose-related decreased platelet adhesion, increased fibrinolysis, and decreased levels of factor VIII. Dextran solutions are associated with the highest incidence of anaphylactic reactions among all of the colloids.

Because of the lack of superior clinically important outcomes and less favorable safety profiles for HES and dextrans compared to albumin, it is decided to use albumin for further volume expansion in P.T.

CARDIOGENIC SHOCK

Shock arising primarily from an abnormality of cardiac function constitutes cardiogenic shock. The causes of cardiogenic shock can be separated largely into cardiomyopathic, arrhythmogenic, and mechanical (Table 17-1), although occasionally patients may have a combination of causes. Regardless of the source, the underlying problem in cardiogenic shock is a decrease in CO that is not caused by a reduction in circulating blood volume. This decrease in CO results in the syndrome of shock, organ dysfunction, and death if measures to restore perfusion are not successful.

The most common cause of cardiogenic shock is LV dysfunction and necrosis as a result of acute myocardial infarction (AMI) (see Chapter 13, Acute Coronary Syndrome). Necrosis of the left ventricle can be the result of a single massive myocardial infarction (MI), numerous smaller events, or severe global cardiac ischemia. Increases in sympathetic tone—seen clinically as increased HR and peripheral vasoconstriction—initially serve to increase CO and maintain arterial pressure. When necrosis exceeds approximately 40% of the LV, normal compensatory responses can no longer maintain CO, and hypotension and hypoperfusion results. In addition to decreased perfusion to vital tissues and organs, the decrease in CO leads to a reduction in the flow of blood through the coronary arteries, which can lead to infarct extension and a further worsening of cardiac performance.

Cardiogenic shock is the leading cause of death in patients hospitalized with AMI. It occurs in 5% to 10% of AMI cases and is more common with ST-elevation versus non-ST-elevation MI.[47] A registry of nearly 2 million patients admitted for ST-elevation MI in the United States from 2003 to 2010 found a 7.9% incidence.[48] The incidence was higher in patients at least 75 years of age, women, and Asian/Pacific Islanders versus less than 75 years of age, men, and other racial/ethnic groups, respectively. Patients with end-stage renal disease appear to be at a higher risk of cardiogenic shock and among those with ST-elevation MI that incidence increased three-fold from 2003 to 2011.[49] The in-hospital mortality for patients experiencing shock decreased 29% from 2003 to 2010, most likely because of coronary reperfusion strategies.[48] The overall mortality rate, however, has remained high

(60%–80%).

Infarction involving the RV can cause cardiogenic shock, even with normal LV systolic function. In this situation, the volume of blood reaching the LV (preload) is reduced because of the inability of the RV to move blood to the left side of the heart. In most patients with cardiogenic shock and RV infarction, significant LV dysfunction is present as well. Arrhythmias are often associated with worsening perfusion, causing or worsening cardiogenic shock, and poor outcomes.

Patients with chronic heart failure (HF) (see Chapter 14, Heart Failure) usually compensate for their poor cardiac function, but acute exacerbations can cause cardiogenic shock with hypotension, hypoperfusion, and organ dysfunction. Cardiac dysfunction occasionally can be seen with severe sepsis because of increases in the production of inflammatory cytokines that have a depressant effect on the myocardium. However, the cytokine-mediated vasodilation and reduction in afterload usually negates the ability to detect the cardiac dysfunction. A similar picture occurs after cardiopulmonary bypass with heart surgery through activation of the inflammatory cascade.

Cardiogenic shock caused by mechanical problems occurs relatively infrequently. In this setting, the systolic function (contractility) of the heart may be normal, but other defects render the heart unable to eject a normal volume of blood. Pericardial tamponade (bleeding into the pericardial sac) and tension pneumothorax (air leakage from the lung into the chest) cause cardiogenic shock by compressing the heart and decreasing the diastolic filling. [Pericardial tamponade and tension pneumothorax are technically obstructive forms of shock as there is an extracardiac process that is impeding forward circulatory flow.] Acute valvular insufficiency or stenosis prevents the normal ejection of blood. Ventricular septal or free wall rupture can occur, often in the setting of AMI, with the reduction in CO related to the inability of the LV to eject a normal volume of blood during systole.

The symptoms of cardiogenic shock are largely the same as for other types of shock. Hypotension and signs of inadequate tissue perfusion, such as confusion, oliguria, tachycardia, and cutaneous vasoconstriction, are present in many patients. Differentiating cardiogenic shock from distributive or hypovolemic shock requires further examination. A history of coronary artery disease or symptoms of MI are important findings. Hypovolemia occurs in up to 20% of patients in cardiogenic shock, but patients frequently have signs of volume overload because the heart cannot move blood through the circulation. Peripheral edema can be seen in the extremities; lung sounds are diminished, and rales may be present as pulmonary edema develops with LV dysfunction. These findings are particularly evident in patients with severe HF.

Because the distinction between cardiogenic and other forms of shock can be difficult to make based on physical examination alone, further testing with invasive hemodynamic monitoring may be required to establish the diagnosis and guide therapy. Table 17-6 lists the common laboratory, electrocardiogram (ECG), and chest radiograph findings, and Table 17-3 lists the common hemodynamic findings in cardiogenic shock. CVP may be easily attained, particularly if the patient already has a central line; other hemodynamic findings will require further monitoring tools (e.g., PA catheter, echocardiography).

Table 17-6

Typical Findings of Early Cardiogenic Shock

- Arterial blood gas (ABG)
  - Hypoxemia secondary to pulmonary congestion with ventilation–perfusion abnormalities
  - Anion gap metabolic acidosis with a compensatory respiratory alkalosis
- Elevated blood lactate levels (which contributes to the acidosis)
- Complete blood count (CBC)
  - Leukocytosis
  - Thrombocytopenia (if disseminated intravascular coagulation is present)
- Elevated cardiac enzymes if myocardial infarction is present
- Electrocardiogram (ECG)–one or more of the following
  - T-wave changes indicating infarction
  - Left bundle branch block
  - Sinus tachycardia
  - Arrhythmia
- Chest radiograph
  - Pulmonary edema or evidence of adult respiratory distress syndrome (ARDS)
- Echocardiography
  - Valvular or mechanical problems if present
  - Normal or decreased ejection fraction
- Hemodynamic monitoring—one or more of the following:
  - Reduced cardiac output
  - Arterial hypotension
  - Elevated pulmonary capillary wedge pressure (PCWP) and central venous pressure (CVP)
  - Elevated pulmonary artery pressure (PAP)
  - Elevated systemic vascular resistance (SVR)

Acute Myocardial Infarction

IMMEDIATE GOALS OF THERAPY AND GENERAL CONSIDERATIONS

CASE 17-3

QUESTION 1: J.S. is a 43-year-old man who presents to the ED complaining of chest pain, tingling down his left arm, diaphoresis, nausea, vomiting, and shortness of breath. His pain has been ongoing for 3 hours and is not relieved by rest. He has no known history of cardiac disease and takes no home medications. His BP is 80/40 mm Hg (by cuff) with a weak pulse of 110 beats/minute. His RR is 24 breaths/minute, and his breathing is shallow. Heart sounds include S_3/S_4 gallops, but no murmurs are heard. The jugular venous pulse is normal. He has diffuse rales over the lower lung fields with moderate wheezing. J.S. is cold and clammy to touch; however, his temperature is normal. He is restless, anxious, and oriented only to person and place. A 3-mm ST-segment elevation is seen on 12-lead ECG in leads I and AVL. Cardiac biomarkers are pending. ABG measurements, on 4 L/minute oxygen via nasal cannula, are the following:

pH, 7.28
$PaCO_2$, 32 mm Hg
PaO_2, 94 mm Hg
HCO_3^-, 15 mEq/L
Hct, 31%

What immediate goals of therapy are necessary to stabilize and treat J.S.?

J.S. has signs of cardiogenic shock with decreased systemic perfusion. His BP is low, HR is elevated, and respiratory status is compromised. J.S. is restless, anxious, and confused, indicating poor cerebral perfusion. His ABG results indicate a component of metabolic acidosis secondary to poor systemic perfusion. The ST-elevation on the ECG is consistent with an acute anterior MI.

As discussed in Chapter 13, Acute Coronary Syndrome, most patients presenting with STEMI are routinely treated with aspirin, a β-blocker, and immediate percutaneous coronary intervention (PCI) if available or, if not, thrombolytic therapy (unless contraindicated).[50] The presence of cardiogenic shock can alter the interventional strategy, however. Patients presenting in cardiogenic shock after MI may progress rapidly to irreversible organ system dysfunction as the compensatory mechanisms fail to maintain tissue perfusion. Treatment of these critically ill patients involves two components: stabilization and definitive treatment. Initial stabilization of the patient must be attained before further evaluation and treatment of the cause of cardiogenic shock can proceed. The goals are to maintain adequate $\dot{D}O_2$ to the tissues and to prevent further hemodynamic compromise. Stabilization includes (a) establishing ventilation and oxygenation (arterial Po_2 should be greater than 70 mm Hg); (b) restoring arterial BP and CO with vasopressors and inotropic agents, if needed; (c) infusing fluids, if hypovolemic; and (d) treating pain, arrhythmias, and acid–base abnormalities, if present.

Administration of oxygen is appropriate for patients who have severe dyspnea, hypoxemia (oxygen saturation below 90%), or persistent or worsening acidemia (pH less than 7.3).[50,51] Improving oxygenation may contribute to improved ventricular performance; however, supplemental oxygen could potentially be harmful by causing increased coronary vascular resistance and infarct size, particularly in normoxic patients.[50,52] Invasive mechanical ventilation is indicated when arterial oxygen saturation cannot be maintained above 90% despite 100% oxygen per facemask. Once the patient is intubated, sedation should be provided to alleviate anxiety and discomfort while cautiously monitoring hemodynamic effects.

The arterial pressure must be increased to provide adequate coronary and systemic perfusion to meet oxygen requirements. Some areas of ischemia in the infarct zone may be depressed but viable, provided myocardial oxygen supply exceeds demand. If the myocardial oxygen demands are not met, however, myocardial tissue necrosis will expand into the area of ischemia. This results in further hemodynamic impairment and initiates a vicious cycle that can lead to intractable pump failure and irreversible shock. To be effective, treatment of cardiogenic shock should favorably influence the balance between oxygen supply and demand in the ischemic zone.

Optimizing preload to improve CO and systemic perfusion is crucial, especially in patients with RV infarction. In patients with severe LV impairment, increasing intravascular volume can worsen pulmonary congestion. J.S. currently has signs of pulmonary congestion and RV infarction is not evident; thus, a fluid challenge must be administered cautiously or withheld until hemodynamic monitoring can be established.

Inotropic agents or vasopressors should be used to increase systemic BP and reestablish coronary perfusion in patients with cardiogenic shock and hypotension. However, vasoactive agents have risk because they can exacerbate ventricular arrhythmias and increase $\dot{V}O_2$ in ischemic myocardium. Therefore, the minimal dose that will provide adequate perfusion pressure should be used. Achieving a MAP of 65 to 70 mm Hg is the immediate goal of therapy, but it should be adjusted based on adequate perfusion (e.g., warm extremities, adequate urine output, improved mental status).[51] Elevation of the MAP to more than 80 mm Hg is unnecessary because coronary blood flow is not significantly changed at this level, but energy expenditure is high.

Correction of metabolic acidosis is best accomplished by treating the underlying cause. Improving tissue perfusion by optimizing oxygen content and increasing CO can eventually restore aerobic metabolism and eliminate lactic acid production. The use of sodium bicarbonate to correct lactic acidosis in cardiogenic shock and other critically ill patients is controversial. Sodium bicarbonate can have numerous adverse effects, such as hypernatremia, paradoxical intracellular acidosis, and hypercapnia; conclusive data on its efficacy are lacking. Bicarbonate therapy is recommended only, if at all, when severe acidemia (pH below 7.2 or HCO_3^- less than 10–12 mEq/L) is present.

Inotropic agents and vasoconstrictors can increase myocardial $\dot{V}O_2$ and potentially extend the area of necrosis in patients with infarct-induced cardiogenic shock. Careful selection and titration of agents that will best preserve myocardium while sustaining systemic arterial pressure and tissue perfusion is essential. Although correction of volume deficits and early pharmacologic support may prevent the extension of myocardial damage, it must be emphasized that exclusive use of these measures does not improve survival. Therefore, drug therapy must be considered only an interim maneuver to preserve myocardial and systemic integrity while further therapeutic interventions and definitive therapy are being considered.

Cardiogenic shock after AMI occurs in only a small percentage of patients, but it carries a high mortality rate. Reperfusion of the occluded artery is of paramount importance in these patients. Two options are available for restoring patency of the artery: thrombolytic therapy and revascularization (PCI or coronary artery bypass grafting [CABG]) (see Chapter 13, Acute Coronary Syndrome).

Thrombolytic therapy in AMI may reduce the incidence of subsequent cardiogenic shock, but its value may be limited in patients who have already experienced shock.[53] The effectiveness of thrombolysis is reduced in this setting, possibly because of reduced delivery of the agent to the coronary artery thrombus as a result of hypotension.[54] The use of an intra-aortic balloon pump (IABP) to augment coronary artery blood flow may improve the efficacy of thrombolytic agents but has not been shown to improve mortality.[55,56]

Early revascularization with PCI or CABG is preferred in patients with cardiogenic shock complicating AMI, irrespective of time delay.[50] In the SHOCK trial, emergency revascularization, compared to immediate medical stabilization (fibrinolysis and IABP), resulted in significantly lower mortality at 1 and 6 years in patients with ST-elevation MI and cardiogenic shock.[53] Long-term mortality was positively correlated with time to revascularization from 0 to 8 hours, confirming that revascularization should be performed as soon as possible. However, a survival benefit for revascularization remains even as long as 54 hours after MI and 18 hours after shock onset.[53] Operator skill is also a consideration, and larger centers with greater experience may have better outcomes than smaller centers. In settings in which interventional cardiac procedures such as percutaneous transluminal coronary angioplasty or stenting are not readily available, insertion of an IABP and thrombolytic agents should not be delayed if indicated.

Postoperative Cardiac Failure

ASSESSMENT BY HEMODYNAMIC PROFILE

CASE 17-3, QUESTION 2: Cardiac catheterization reveals an acute occlusion of the proximal left circumflex artery, but a percutaneous coronary intervention was unable to be performed for J.S. He undergoes emergent CABG and arrives in the ICU sedated, intubated, and receiving mechanical ventilation with 50% inspired oxygen. Several hours after admission to the ICU his BP and urine output have fallen and his skin is mottled and cool. Urine output has fallen from 0.8 to 0.2 mL/kg/hour in the last hour. The chest tube output has been stable at 50 mL/hour. His current hemodynamic profile is as follows:

BP (S/D/M), 86/44/58 mm Hg
HR, 105 beats/minute
CO, 3.0 L/minute
CI, 1.7 L/minute/m^2
SvO_2, 48%

CVP, 14 mm Hg
PA pressure (S/D), 41/24 mm Hg
PCWP, 24 mm Hg
SVR, 1,570 dyne·s·cm^{-5}

What is your assessment of J.S.'s clinical status and hemodynamics?

Clinically, J.S. has signs of hypoperfusion manifested by low urine output; mottled, cool skin; and metabolic acidosis. His decreased Svo_2 shows that he has impaired perfusion owing to his low $\dot{D}O_2$. Evaluation of his hemodynamics will help determine a potential cause for his hypoperfusion and assist with the decision about appropriate therapeutic interventions to prevent his condition from worsening to serious organ dysfunction and death.

Possible causes of shock in cardiac surgery patients include blood loss, excessive vasodilation from medications or cardiopulmonary bypass-induced inflammation, cardiac ischemia-reperfusion injury, valvular dysfunction, tamponade, heart failure, or perioperative MI. Another concern is "stunning" of the myocardium caused by surgical trauma, which can take hours to days to resolve.

Hypovolemia should always be evaluated first when assessing hemodynamic profiles. Using vasopressor or inotropic agents in the setting of hypovolemia is rarely effective and could cause further hypotension or serious adverse effects (e.g., cardiac arrhythmias). Also, correction of hypovolemia is relatively straightforward and can be accomplished rapidly. Most patients require no more than 2 to 3 L of crystalloid after cardiac surgery, especially once rewarming is complete. J.S.'s tachycardia, low urine output, low BP, and low CO could indicate volume depletion. However, his Hct is adequate, and he has an elevated CVP, PAP, and PCWP, suggesting that he is not hypovolemic.

Excessive vasodilation is also unlikely in J.S., given that his calculated SVR (afterload) is above normal range. Cardiac tamponade should always be considered after cardiac surgery, and it is usually manifested by very high CVP, PCWP, and PA pressures, with significant decreases in CO and BP. Diminished or muffled heart sounds and an inappropriately fluctuating BP with respirations (pulsus paradoxus) will usually accompany an equalization of diastolic pressures during cardiac tamponade. J.S.'s CVP and PCWP are not as high as would be expected in pericardial tamponade, and his chest tube output has remained consistent, suggesting that blood is not accumulating.

Based on this hemodynamic profile, it appears that J.S. is in shock because of acute HF, most likely from postoperative myocardial dysfunction, although he should also be evaluated for myocardial ischemia or infarction and to rule out early cardiac tamponade. This evaluation should not delay the initiation of therapy.

Patients with cardiogenic shock from an acute event (such as an MI) are usually more critical than patients who have an acute exacerbation of chronic HF. Patients with HF have compensated with time for the increases in preload and reduced CO, but patients such as J.S. have not had time to develop compensatory mechanisms. His severely depressed CO should be treated immediately to prevent further decompensation.

THERAPEUTIC INTERVENTIONS

CASE 17-3, QUESTION 3: The chest radiograph shows moderate pulmonary edema, and rales were heard on auscultation. His ABG measurements on mechanical ventilation with 50% inspired oxygen are pH 7.3, $PaCO_2$ 38 mm Hg, PaO_2 90 mm Hg, and HCO_3^- 18 mEq/L. Tamponade is not evident on the radiograph. The ECG shows ST-T-wave changes with some resolution of ST-elevation in leads I and AVL, but no indication is seen of a new AMI. Cardiac biomarkers are pending. BP and CO need to be improved to increase perfusion to vital organs. Three therapeutic interventions are available: fluid challenge, vasodilators, and inotropic agents. How would these choices affect J.S.'s ventricular function?

Fluid Challenge (Increase Preload)

Augmentation of preload with a fluid challenge to improve CO is the first option. However, J.S. has signs of pulmonary edema on chest radiograph, PCWP is 24 mm Hg, and Pao_2 is 90 mm Hg on 50% inspired oxygen. Increasing the PCWP above 18 mm Hg usually does not result in further benefit.[57,58] Therefore, giving volume might increase the pulmonary vascular hydrostatic pressure and worsen his pulmonary edema. If a fluid challenge is attempted to enhance preload, 250 to 500 mL of NS solution should be given over 20 to 30 minutes while continuously monitoring the hemodynamic profile and for volume overload. If the PCWP rises but the CO does not improve, fluid challenges should be discontinued. Elevating the preload without appreciably improving CO increases LV wall tension, which is a major determinant of myocardial $\dot{V}O_2$; consequently, myocardial ischemia could develop. Although J.S. has signs of pulmonary edema, diuretics to reduce his volume overload can be detrimental to his CO and BP and should not be used until J.S.'s hemodynamics and signs of hypoperfusion have improved.

Vasodilators (Preload and Afterload Reduction)

A peripheral venodilator will decrease pulmonary venous congestion by reducing preload (CVP and PCWP) and pulmonary vascular hydrostatic pressure. With myocardial ischemia, a reduction of the LV filling pressure may improve subendocardial blood flow, reduce the myocardial wall tension, and reduce the LV radius. The resultant decrease in myocardial $\dot{V}O_2$ will help prevent further depression of cardiac function.

In patients with LV failure, arterial resistance is also elevated because of a reflex increase in sympathetic tone in response to a fall in systemic arterial pressure. In LV failure, CO is inversely related to resistance to outflow from the LV. Lowering an elevated SVR (afterload) will decrease resistance to ventricular ejection and shift the ventricular function curve up and to the left, depending on whether an arterial, venous, or mixed vasodilator is used, thereby improving cardiac performance at a lower filling pressure (Fig. 17-4).

J.S. appears to have LV failure with elevations in PCWP and SVR. Vasodilator therapy in this setting will likely improve his CO and, therefore, increase the $\dot{D}O_2$ to the tissues and prevent organ dysfunction. The major risk of vasodilator therapy in J.S., however, is further reduction of an already low MAP. Although the reduction in BP may be offset by an increase in CO, a significant drop in arterial BP could occur, which could decrease perfusion to vital organ systems and exacerbate myocardial ischemia by reducing coronary perfusion pressure. Vasodilator therapy should be reserved for situations of LV failure with elevations in PCWP and SVR and a SBP greater than 90 mm Hg.

Inotropic Support

A rapid-acting inotropic agent also can be used to increase myocardial contractility if the CO remains low or inadequate with signs of tissue hypoperfusion after optimization of the volume status.[1] This intervention shifts the ventricular function curve upward and slightly to the left (Fig. 17-4). The disadvantage of this intervention is that improved CO is accompanied by increased myocardial oxygen demand. Depending on the agent selected, three of the determinants of myocardial $\dot{V}O_2$ could be elevated: HR, contractility, and ventricular wall tension. Therefore, inotropic support is directed at establishing or maintaining a reasonable arterial pressure and ensuring adequate tissue perfusion by improving the CO.

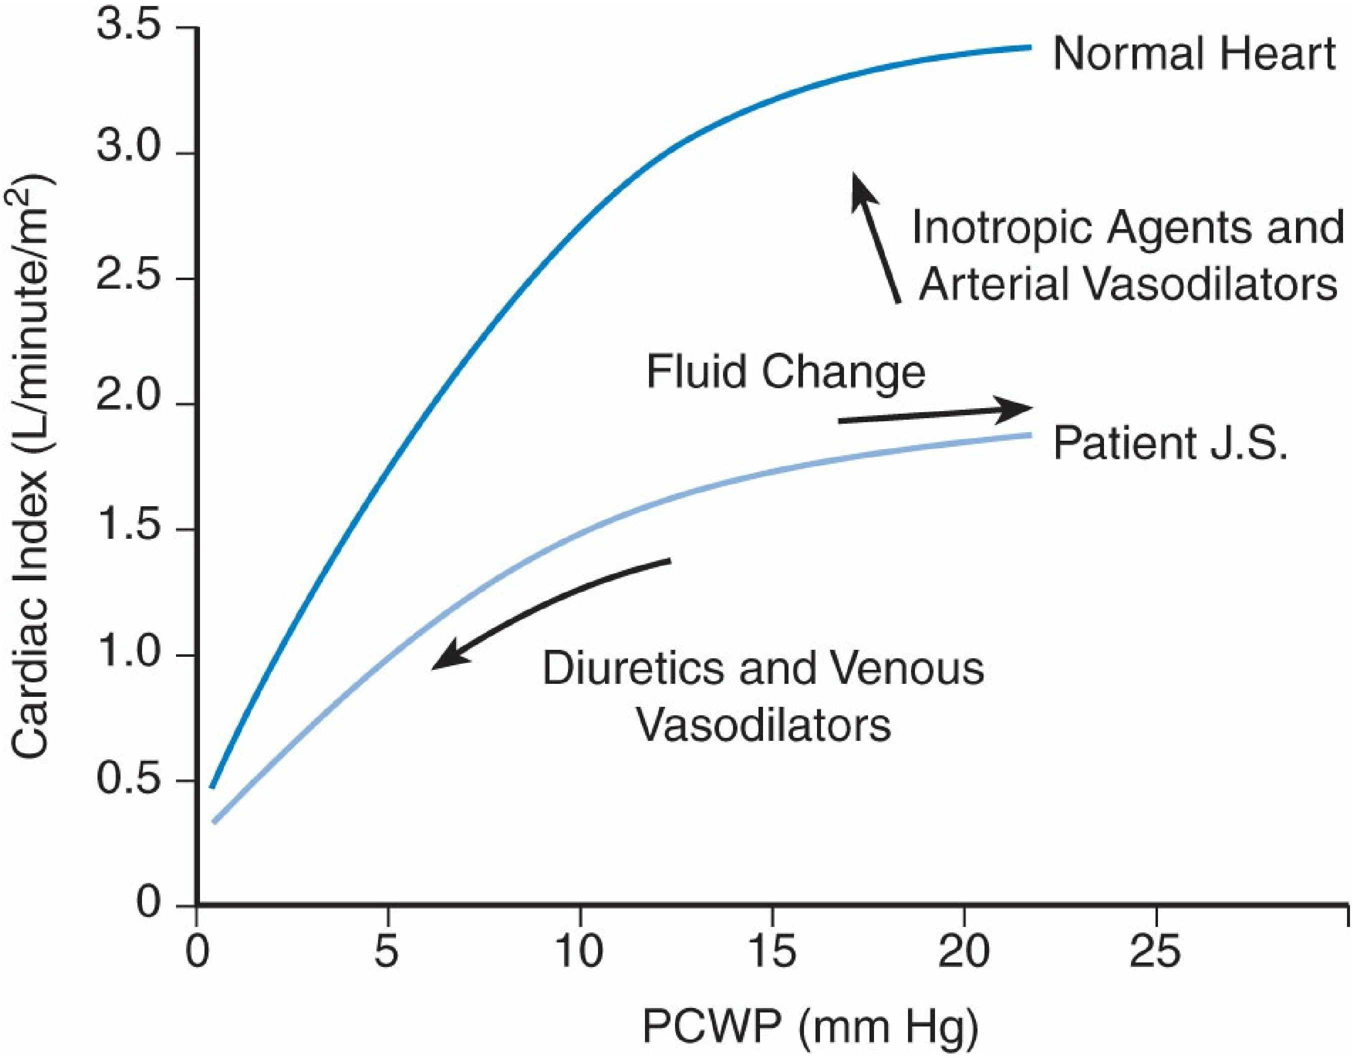

Figure 17-4 Ventricular function curve for J.S. PCWP, pulmonary capillary wedge pressure.

In summary, the most appropriate therapeutic intervention for J.S. at this time would be inotropic support. The PCWP is elevated, suggesting that the preload has been maximized; therefore, fluid may worsen J.S.'s pulmonary edema. Although J.S.'s SVR is elevated (1,570 dyne·s·cm^{-5}), his BP is low; therefore, initial use of a peripheral vasodilator could jeopardize perfusion. Thus, an acceptable initial therapeutic intervention to improve CO and tissue perfusion is inotropic support. After a reasonable BP has been established, addition of a peripheral vasodilator could be considered to further enhance CO if needed, and diuretics added to reduce his pulmonary edema.

INOTROPIC AGENTS

CASE 17-3, QUESTION 4: Which inotropic agent is the best choice for J.S.?

Dopamine

Dopamine, a precursor of norepinephrine, has inotropic, chronotropic, and vasoactive properties, all of which are dose dependent (Table 17-7). The distinct ranges noted for dopamine activity are generalizations; responses noted in clinical practice will be patient specific. At less than 5 mcg/kg/minute, dopamine stimulates dopaminergic receptors primarily in the splanchnic, renal, and coronary vascular beds. The effect on dopaminergic receptors is not blocked by β-blockers, but is antagonized by dopaminergic-blocking agents such as the butyrophenones and phenothiazines. Depending on the clinical state of the patient, low dosages of dopamine may slightly increase myocardial contractility, but it usually will not alter HR or SVR significantly.

At 5 to 10 mcg/kg/minute, the improved cardiac performance produced by dopamine is through direct stimulation of β_1-adrenergic receptors and indirectly through release of norepinephrine from nerve terminals. Increased β_1-adrenergic receptor stimulation increases SV (inotropic effect), HR (chronotropic effect), and consequently CO. These cardiac effects can be blocked by β-blockers. As infusion rates increase above 5 mcg/kg/minute, the α-adrenergic receptors are activated. At this dosage, the vasoactive effects on peripheral blood vessels are unpredictable and depend on the net effect of β_1-adrenergic stimulation, α-adrenergic stimulation, and reflex mechanisms. MAP and PCWP usually will rise. The increased HR, along with the elevated PCWP in J.S., could adversely affect the myocardial oxygen supply to demand ratio. However, it is hoped the increase in coronary blood flow (caused by the rise in arterial pressure) and the decrease in LV chamber size (associated with the increase in contractility) would tend to offset the increase in myocardial oxygen requirements.

Table 17-7

Inotropic Agents and Vasopressors

Drug	Usual Dose	Receptor Sensitivity			Pharmacologic Effect			
		α1	β1	β2	VD	VC	INT	CHT
Dobutamine	2–10 mcg/kg/minute	+	++++	++	+	+	+++[a]	+
	>10 mcg/kg/minute	++	++++	+++	++	+	++++[a]	++
Dopamine	<5 mcg/kg/minute[b]	0	+	0	+	0	++	+
	5–10 mcg/kg/minute[b]	0/+	++++	++	+	+	+++	++
	10–20 mcg/kg/minute[b]	+++	++++	+	0	+++	+++	+++
Epinephrine[c]	<0.1 mcg/kg/minute	+	++++	+++	+	+	++++[a]	++
	0.1–2 mcg/kg/minute	+++	++++	+++	0	+++	+++[a]	+++

	>2 mcg/kg/minute	++++	++	+	0	++++	++[a]	+++
Isoproterenol	0.01–0.1 mcg/kg/minute	0	++++	++++	+++	0	++++	++++
Milrinone	Possible 50 mcg/kg bolus, then 0.125–0.75 mcg/kg/minute	0	0	0	+++[d]	0	+++	0
Norepinephrine[c]	0.02–3 mcg/kg/minute[f]	++++	+++	+	0	++++	+[e]	++
Phenylephrine	0.5–5 mcg/kg/minute[f]	++++	0	0	0	++++	0	0
Vasopressin[g]	0.03–0.04 units/minute[h]	0	0	0	0	++++	0	0

[a] Dobutamine, milrinone, and epinephrine have more inotropic effect than dopamine.

[b] Dopamine stimulates dopaminergic receptors at all doses, causing vasodilation in the splanchnic and renal vasculature.

[c] Epinephrine has predominant inotropic effects; norepinephrine has predominant vasoconstrictive effect. Epinephrine may vasodilate at low dosages, vasoconstrict at high dosages.

[d] Milrinone inhibits phosphodiesterase-3, leading to increased contractility of the myocardium and vasodilation of vascular smooth muscle.

[e] Cardiac output unchanged or may decline because of vagal reflex responses that slow the heart.

[f] Highly variable, titrate to desired MAP

[g] Vasopressin stimulates V_{1a} receptors to cause vasoconstriction in the periphery.

[h] Dosing for sepsis; in other vasodilatory conditions, it may be titrated from 0.01 to 0.1 units/minute.

CHT, chronotropic; INT, inotropic; MAP, mean arterial pressure; VC, peripheral vascular vasoconstriction; VD, peripheral vascular vasodilation.

At doses greater than 10 mcg/kg/minute, dopamine primarily stimulates peripheral α-adrenergic receptors. SVR increases, splanchnic and renal blood flow decreases, and LV filling pressure is raised. Cardiac irritability is a potential complication, and the overall myocardial $\dot{V}O_2$ is increased. The increase in SVR limits CO; thus, infusion rates should be limited to less than 15 mcg/kg/minute in patients with cardiac failure.[59]

In a recent trial of 1,679 patients with shock, who were randomized to dopamine or norepinephrine for blood pressure support, there was no significant difference in the primary outcome of 28-day mortality.[60] However, patients receiving dopamine had more arrhythmic events and a prespecified subgroup analysis showed an increased mortality rate in 280 patients with cardiogenic shock. Although these findings may have been because of chance and randomization was not stratified, these findings warrant consideration before selecting dopamine for J.S. and highlight the need for more studies comparing catecholamines in cardiogenic shock.

Dobutamine

Dobutamine, a synthetic catecholamine, is a potent positive inotropic agent with dose-dependent but predominant direct β_1-agonist effects and weak β_2- and α_1-adrenergic effects. With greater β_2-vasodilatory than α_1-vasoconstrictive actions, dobutamine reduces systemic and pulmonary vascular resistance. The reduction in SVR may be caused by a reflex decrease in vasoconstriction secondary to enhanced CO. Unlike dopamine, dobutamine does not release endogenous norepinephrine or stimulate renal dopaminergic receptors.[61]

Studies assessing dobutamine in cardiac failure demonstrate consistent increases in CO and SV, with reductions in PCWP and SVR. The reduction in filling pressures, as indicated by a lowered PCWP, results in a decrease in LV wall tension and myocardial $\dot{V}O_2$. Consequently, coronary perfusion pressure and myocardial oxygen supply is improved.

Compared with dopamine, dobutamine has equal or greater inotropic action. Dobutamine lowers PCWP and SVR with increasing doses, whereas dopamine may increase PCWP and SVR with increasing doses.[62] The effect on HR is variable; however, evidence suggests that dobutamine is less chronotropic than dopamine at lower infusion rates. In the clinical setting, dobutamine may be preferred in patients with depressed CO, elevated PCWP, and increased SVR with mild hypotension (SBP above 70 mm Hg) and no signs or symptoms of shock. The increase in CO may not be sufficient to raise the BP in a patient who initially is moderately to severely hypotensive (SBP below 70 mm Hg) or with signs or symptoms of shock. Dopamine may be recommended in patients with mild hypotension and symptoms of shock, whereas norepinephrine is reserved for patients with a SBP below 70 mm Hg.[63,64] Given the recent concerns of increased mortality with dopamine monotherapy in patients with cardiogenic shock, the combination of dopamine or norepinephrine with dobutamine may be preferred in patients with depressed CO, normal or moderately elevated PCWP, and moderate or severe hypotension.[59,60,64]

Epinephrine

Similar to dopamine and dobutamine, epinephrine has dose-dependent hemodynamic effects (Table 17-7). At lower infusion ranges (less than 0.1 mcg/kg/minute) epinephrine stimulates β_1-adrenergic receptors, causing increases in HR and contractility. As the dose increases, more α_1-receptor stimulation occurs, resulting in vasoconstriction and corresponding increases in SVR.

The favorable hemodynamic effects (increased CO and BP) make low-dose epinephrine an attractive option for J.S.; however, epinephrine can induce hyperglycemia through gluconeogenesis and has been shown to increase lactate levels compared with other vasopressors and inotropic agents.[65] J.S. already has signs of acidosis (pH 7.28, HCO_3^- 15 mEq/L), and increased lactic acid production by epinephrine could be detrimental to his organ function. Epinephrine should be reserved for patients with a markedly depressed CO in conjunction with severe hypotension.

In summary, very few comparable studies of inotropic agents in this setting have been conducted; thus, the selection of agent is often based on the expected clinical benefit as well as individual experience with the drugs.[66] None of the choices are without risk as they could adversely affect the myocardial oxygen supply to demand ratio and could further extend the area of ischemia or necrosis. J.S. would benefit from an increase in his CO, as well as in his MAP. The clinician elects to start J.S. on dobutamine and dopamine infusions.

SELECTION AND INITIATION OF THERAPY

CASE 17-3, QUESTION 5: At what doses should you initiate a dobutamine and dopamine infusion in J.S.? What therapeutic outcomes are anticipated at these doses and during what time? What adverse effects may be encountered with these infusions?

J.S. has a MAP of 58 mm Hg, CI of 1.7 L/minute/m^2, PCWP of 24 mm Hg, and HR of 105 beats/minute. Goals of therapy are to increase the CI to at least 2.5 L/minute/m^2, maintain a MAP of at least 70 mm Hg (preferably closer to 80 mm Hg, depending on clinical signs of hypoperfusion), reduce the PCWP to 12 to 18 mm Hg, and maintain an HR of less than 125 beats/minute. A urine output of at least 0.5 mL/kg/hour is desirable. Reasonable initial infusion rates would be dopamine 5 mcg/kg/minute and dobutamine 2 mcg/kg/minute. These doses should increase cardiac contraction and CO, resulting in an increase in renal blood flow. The onset of effect is rapid and the half-life short (approximately 2 minutes) for both agents, with steady-state conditions generally achieved within 10 minutes of initiation of therapy. This allows dose titration every 10 minutes based on patient tolerance.

Because the onsets of action are within minutes, J.S. can be reevaluated and the infusion rates can be alternately titrated upward by 1 to 2 mcg/kg/minute every 10 minutes, depending on the hemodynamic data. The response to both agents is highly variable among patients; thus, careful titration using the lowest effective infusion rates is advised.

Adverse effects encountered with both infusions include increased HR, angina, arrhythmias, headache, tremors, nausea, and vomiting. The increases in contractility and HR caused by dobutamine and dopamine pose additive risk of tachyarrhythmias and can increase myocardial $\dot{V}O_2$, leading to ischemia in patients with coronary artery disease.

Dobutamine could lower the MAP, adversely affecting coronary perfusion pressure. Another limiting factor to dobutamine is tolerance to its hemodynamic effects with long-term continuous use. A decline in CO and HR has been seen after prolonged infusion and is most likely caused by down-regulation of β_1-receptors. Of concern, evidence suggests that inotropic agents can be associated with an increased risk of mortality in patients with HF despite the improvement of symptoms and hemodynamic indices.[67]

Dopamine might elevate the PCWP, thereby decreasing coronary perfusion pressure. Extravasation of large amounts of dopamine during infusion can cause ischemic necrosis and sloughing. At higher dosages, α_1-adrenergic effects are more prominent, causing peripheral arterial vasoconstriction and increases in afterload, preload, and myocardial oxygen demand as well as ischemia.

CASE 17-3, QUESTION 6: Dobutamine and dopamine are titrated from 2 to 4 mcg/kg/minute and 5 to 6 mcg/kg/minute, respectively, in J.S. during the next 2 hours. A repeat chest radiograph shows slight worsening of pulmonary edema. The following hemodynamic profile is obtained (previous values are in parentheses):

BP (S/D/M), 105/60/75 mm Hg (86/44/58 mm Hg)
HR, 140 beats/minute (105 beats/minute)
CO, 5.3 L/minute (3 L/minute)
CI, 3 L/minute/m^2 (1.7 L/minute/m^2)
CVP, 11 mm Hg (14 mm Hg)
PCWP, 22 mm Hg (24 mm Hg)
SVR, 1,493 dyne·s·cm^{-5} (1,570 dyne·s·cm^{-5})
Urine output, 0.4 mL/kg/hour (0.2 mL/kg/hour)
Hct, 33% (31%)

Do these data indicate a favorable or adverse hemodynamic effect from dobutamine and dopamine in J.S.?

Dobutamine at 4 mcg/kg/minute and dopamine at 6 mcg/kg/minute have established a trend in the desired direction for CI; however, the HR has increased significantly. The SVR and PCWP have not changed appreciably, and the urine flow has increased. The SV (CO/HR) has only increased from 28 to 38 mL/beat; thus, the increase in CO has resulted from both the chronotropic and the inotropic effects of these agents. As a net response, the dobutamine and dopamine have most likely adversely affected the myocardial oxygen supply to demand ratio; however, this cannot be established definitively. J.S. should be monitored closely for signs of myocardial ischemia.

CHANGING THERAPY

CASE 17-3, QUESTION 7: The clinician decides that an HR of 140 beats/minute is unacceptable in J.S., who presented with an AMI. Subsequent attempts to taper the dobutamine to lessen the induced tachycardia without dropping the CI and perfusion pressure are unsuccessful. Milrinone is suggested as an alternative to dobutamine. What hemodynamic changes would you expect with milrinone in J.S.? Does milrinone offer any advantages compared with dobutamine?

Milrinone increases intracellular AMP levels by inhibiting phosphodiesterase-3 within the sarcoplasmic reticulum of cardiac myocytes and vascular smooth muscle, leading to increased contractility of the myocardium and vasodilation of vascular smooth muscle. The increased CO and decreased SVR are accompanied by an increased lusitropic effect. Milrinone produces fewer chronotropic and arrhythmogenic effects than the catecholamines but, like dobutamine, can decrease SVR and cause hypotension. Moreover, milrinone has a longer half-life than dobutamine, making it difficult to use as monotherapy for cardiogenic shock. The combination of

---

dopamine with milrinone would offset some of milrinone's hypotensive effects. Although milrinone has not been studied in patients who are post-AMI with cardiogenic shock, it could be beneficial in patients with adequate BP, who have down-regulated β receptors (chronic heart failure or beta agonist use), recently received β-blockade, or with catecholamine dose-limiting arrhythmias.

Dobutamine has equivalent or greater inotropic action than dopamine and, as mentioned above, dobutamine causes less tachycardia, so it may be better to remove dopamine in this patient. A decrease of 20% of the current dopamine infusion rate (1 to 2 mcg/kg/minute) every 10 to 15 minutes is reasonable. Just as with upward titration of therapy, steady state should be achieved within 10 minutes. When tapering vasoactive agents, it is prudent, however, to let the patient stabilize hemodynamically at new infusion rates for a period that exceeds the time to achieve a new steady-state plasma concentration. After each reduction in the infusion rate, hemodynamic data can be assessed. The major difference between the two agents is the effect of dopamine on α_1-receptors. With dobutamine's greater clinical effect on β_2-receptors compared to α_1-receptors, J.S. may experience a decrease in the SVR. A decreased SVR should allow for an increased CI, but J.S. should be monitored carefully as his MAP is relatively low and any major reduction in SVR could lead to further BP reduction.

CASE 17-3, QUESTION 8: Dopamine is tapered off and dobutamine is increased to 5 mcg/kg/minute for J.S. His HR decreased to 105 to 110 beats/minute within the next hour. Despite these changes and initiation of ventilatory support by tracheal intubation, J.S. continues to show signs of deterioration with progressive obtundation and loss of bowel sounds. His systemic arterial pressure has continued to decline. Preload reduction was attempted previously with nitroglycerin; however, the BP reduction was intolerable. A repeat hemodynamic profile shows the following values (previous values in parentheses):

BP (S/D/M), 86/40/55 mm Hg (105/60/75 mm Hg)
HR, 132 beats/minute (105 to 110 beats/minute)
CO, 3.2 L/minute (5.3 L/minute)
CI, 1.8 L/minute/m^2 (3 L/minute/m^2)
SvO_2, 42% (48%)
CVP, 16 mm Hg (11 mm Hg)
PCWP, 28 mm Hg (22 mm Hg)
SVR, 992 $dyne \cdot s \cdot cm^{-5}$ (1,493 $dyne \cdot s \cdot cm^{-5}$)
Urine output, 0.1 mL/kg/hour (0.4 mL/kg/hour)
PaO_2, 75 mm Hg (90 mm Hg)

$PaCO_2$, 42 mm Hg (38 mm Hg)
pH, 7.24 (7.3)
HCO_3^-, 17 mEq/L (18 mEq/L)

The ECG shows atrial tachycardia with occasional premature ventricular contractions. What therapeutic alternatives can be considered at this time?

J.S. is still in severe cardiogenic shock, and his tissue perfusion continues to deteriorate as evidenced by a further reduction in urine output, a loss of bowel sounds, continuing acidosis, and obtundation. Because his systemic arterial pressure and tissue perfusion have declined, additional support with a potent vasopressor and the insertion of an IABP or other percutaneous ventricular assist device are indicated. The combination of dopamine and dobutamine previously resulted in intolerable tachycardia, so other therapies should be considered.

Norepinephrine

Norepinephrine is a potent α-adrenergic agonist that vasoconstricts arterioles at all infusion rates, thereby increasing SVR. Thus, systemic arterial and coronary perfusion pressures both rise. Norepinephrine also stimulates β_1-adrenergic receptors to a lesser extent, resulting in increased contractility and SV. However, HR and CO usually remain constant or may decrease secondary to the increased afterload, and baroreceptor-mediated reflex increases in vagal tone. Although coronary perfusion pressure is enhanced as a result of the elevation in diastolic pressure, myocardial $\dot{V}O_2$ also is increased. Consequently, myocardial ischemia and arrhythmias may be exacerbated and LV function further compromised.

Infusions of norepinephrine are begun at 0.01 to 0.05 mcg/kg/minute and titrated upward to achieve a MAP of 65 to 70 mm Hg. Adverse effects of norepinephrine are related mostly to excessive vasoconstriction and compromise of organ perfusion. Administration should be through a central IV line because local subcutaneous necrosis and sloughing can result from peripheral IV extravasation. Prolonged infusion of larger doses will transiently exert a beneficial effect by diverting blood flow from the peripheral and splanchnic vasculature to the heart and brain; however, this ultimately can compromise capillary perfusion to the extent that end-organ failure, particularly renal failure, ensues.

Again, it must be emphasized that pharmacologic support for J.S., particularly the use of norepinephrine, is only an interim maneuver to temporarily maintain hemodynamic function. J.S. should continue to be monitored for signs of myocardial ischemia and the need for further revascularization procedures. Patients who cannot be stabilized with pharmacologic intervention, and in whom systemic or myocardial perfusion is becoming compromised, may require further support through insertion of a mechanical circulatory assist device.

Mechanical Circulatory Support

When drug therapy is ineffective at stabilizing patients in cardiogenic shock, mechanical intervention should be considered. Mechanical interventions can rapidly stabilize patients with cardiogenic shock, especially those with global myocardial ischemia or infarction complicated by mechanical defects, such as papillary muscle rupture or ventricular septal rupture. Sometimes combined inotropic support and intra-aortic balloon counterpulsation are required to maintain an acceptable BP (MAP above 65 mm Hg) and CI (greater than 2.2 L/minute/m^2).

The IABP has been in use for more than 40 years and remains the most commonly used mechanical assist device. It is designed to improve coronary arterial perfusion pressure and reduce afterload, providing short-term reperfusion of the ischemic myocardium.[68] A 20- to 50-mL balloon catheter is inserted into an artery (usually femoral) and advanced to the proximal descending aorta. Balloon inflation and deflation are synchronized with the ECG to inflate during diastole and deflate at the onset of systole. The inflated balloon in diastole increases coronary perfusion by elevating the mean aortic pressure. The rapid deflation of the balloon at the onset of systole decreases afterload and modestly improving CO.[68] The enhanced myocardial perfusion provided by IABP may reduce vasopressor requirements, thereby further decreasing myocardial $\dot{V}O_2$. Occasionally, IABP augmentation is sufficient to allow the institution of vasodilators (e.g., nitroprusside) or inodilators (e.g., milrinone). IABP support should be discontinued as soon as the patient stabilizes or complications develop. Complications associated with the IABP increase with longer duration of use and include vascular injury, thrombocytopenia from the mechanical destruction of platelets, and limb ischemia because of reduced blood flow in the artery into which the IABP catheter is inserted. Heparin anticoagulation is usually given with IABP because the device has a large, thrombogenic surface area. Infectious complications are uncommon when the use is limited to less than 7 days. Reviews of clinical studies investigating the use of the IABP in cardiogenic shock have found no differences in 30-day mortality and an increase in the risk of bleeding complications and stroke.[68,69] Despite the lack

of evidence, this device is recommended as reasonable to consider for patients after ST-elevation MI and is commonly used to support patients with cardiogenic shock.[50]

Newer devices have been developed (TandemHeart, Impella) that augment CO directly and decrease the load on the LV.[68] These small pumps are placed percutaneously in the cardiac catheterization laboratory, avoiding major cardiac surgery. They are best used for temporary circulatory support until more definitive therapy is available. Systemic anticoagulation is required with these devices. Complications of the TandemHeart include vascular injury, limb ischemia, cardiac tamponade, thrombo- or air-embolism, and hemolysis. The most common adverse effects of the Impella include vascular injury, thrombosis, thrombocytopenia, bleeding, and hemolysis.

Advanced circulatory assist devices are evolving rapidly and are available in centers with access to cardiac surgical procedures. Most patients currently receive second- or third-generation, continuous flow devices (HeartMate II, Jarvik 2000, HeartWare) because of their superior survival rates and lower incidence of adverse events.[70] Mechanical assistance with these devices is used for patients with cardiogenic shock who need support while awaiting definitive, corrective therapy or as a bridging mechanism before cardiac transplantation. An improvement in survival rates with newer generation devices has allowed their long-term use as destination therapies in patients with severe cardiac failure despite optimal pharmacotherapy that are not transplant candidates. The high cost of these devices and need for experienced physicians will undoubtedly limit their use to only the most severely ill patients.

In summary, J.S.'s condition has continued to deteriorate since his admission to the ICU. Attempts at stabilizing his hemodynamic parameters with dopamine and dobutamine have failed. This is evidenced by inadequate tissue perfusion, which is reflected clinically by his continued lactic acidosis, decreased urine output, reduced bowel sounds, and central nervous system obtundation. Norepinephrine and epinephrine should be considered at this point to restore intra-arterial pressure and tissue perfusion. Intra-aortic counterpulsation can provide synergistic temporary support for J.S.

SEPTIC SHOCK

Distributive Shock

Distributive shock is characterized by an overt loss of vascular tone, causing acute tissue hypoperfusion. Although numerous events such as anaphylaxis or neurogenic causes can initiate distributive shock, most cases are readily reversed by supportive measures and treatment or elimination of the underlying cause.

SEPTIC SHOCK

Distributive shock secondary to sepsis, or septic shock, is associated with a high mortality rate, reflecting the limited therapeutic options available at this time. Over 1,500,000 cases of sepsis syndrome are seen annually in the United States. Mortality rates are as high as 50%.[71] The combination of degree of organ dysfunction and number of failing organs is the strongest predictor of death. Epidemiologic studies show that approximately 25% of cases of sepsis syndrome eventually result in septic shock. It has been projected that the incidence of sepsis will increase 1.5% per year mainly because of the disproportionate growth of the elderly in the US population, increasing burden of chronic health conditions, rising numbers of immunocompromised patients, and multidrug-resistant infections.[3,4,71–73]

The guidelines committee of the Surviving Sepsis Campaign—an international consortium of professional societies involved in critical care, infectious diseases, and emergency medicine—defines sepsis syndrome as life-threatening organ dysfunction caused by a dysregulated host response to infection (see Table 17-8 for definitions).[4] Organ dysfunction is identified as an acute change in total Sequential Organ Failure Assessment (SOFA) score by at least 2 points consequent to the infection (see Table 17-9 for SOFA calculation). In patients without preexisting organ dysfunction, the baseline SOFA score is assumed to be zero. Persons with an overall SOFA score of at least 2 may have a 25-times higher risk of mortality compared to those with a score less than 2. A new bedside clinical score termed quickSOFA (qSOFA) can easily identify persons that are more likely to have poor outcomes. Adults with suspected infection are expected to fare worse if they have at least two of three clinical criteria: RR of 22 breaths/minute or greater, altered mentation (Glasgow Coma Scale score <15), or SBP of 100 mm Hg or less. When hypotension persists despite adequate fluid resuscitation and requires vasopressor support to maintain a MAP of at least 65 mm Hg while also having a serum lactate level above 2 mmol/L, it is termed septic shock. Septic shock is associated with a higher risk of mortality. Persons most at risk for septic shock are those who are immunocompromised or have underlying conditions that render them susceptible to bloodstream invasion. Groups at risk include neonates, the elderly, patients with acquired immune deficiency syndrome, alcoholics, childbearing women, and those undergoing surgery or who have experienced trauma. Other predisposing factors include coexisting diseases such as diabetes mellitus, malignancies, chronic hepatic or renal failure, and hyposplenism; exposure to immunosuppressant drugs and cancer chemotherapy; and procedures such as insertion of urinary catheters, endotracheal tubes, and IV lines.

Table 17-8

International Sepsis Definitions Task Force Definitions

Infection	Pathologic process caused by the invasion of normally sterile tissue or fluid or body cavity by pathogenic or potentially pathogenic microorganisms. (Noted exception: Clostridium difficile colitis does not occur in a sterile colon)
Bacteremia	The presence of viable bacteria in the blood.
Sepsis	Life-threatening organ dysfunction caused by a dysregulated host response to infection.
Organ dysfunction	Identified as an acute change in total SOFA score ≥2 points consequent to the infection.
Septic shock	A subset of sepsis in which underlying circulatory and

	cellular/metabolic abnormalities are profound enough to substantially increase mortality. Persistent sepsis-induced hypotension requiring vasopressors to maintain MAP ≥65 mm Hg and having a serum lactate level >2 mmol/L despite adequate fluid resuscitation. Patients who are on inotropic or vasopressor agents may not be hypotensive at the time that perfusion abnormalities are measured.
Multiple organ dysfunction syndrome	Presence of progressive organ dysfunction in an acutely ill patient, such that homeostasis cannot be maintained without intervention.

MAP, mean arterial pressure; SOFA, Sequential Organ Failure Assessment.

Table 17-9

Sequential Organ Failure Assessment Score

	Score				
System	**0**	**1**	**2**	**3**	**4**
PaO_2/FiO_2, mm Hg	≥400	<400	<300	<200 with respiratory support	<100 with respiratory support
Platelets, $\times 10^3/\mu L$	≥150	<150	<100	<50	<20
Bilirubin, mg/dL	<1.2	1.2–1.9	2–5.9	6–11.9	>12
Cardiovascular	MAP ≥ 70 mm Hg	MAP <70 mm Hg	DA < 5[a] or DOB (any dose)	DA 5.1–15 or Epi ≤0.1 or NE ≤0.1[a]	DA > 15 or Epi > 0.1 or NE > 0.1[a]
GCS score[b]	15	13–14	10–12	6–9	<6
Creatinine, mg/dL	<1.2	1.2–1.9	2–3.4	3.5–4.9	>5
Urine output, mL/day				<500	<200

DA, dopamine; DOB, dobutamine; Epi, epinephrine; FiO_2, fraction of inspired oxygen; GCS, Glasgow Coma Scale; MAP, mean arterial pressure; NE, norepinephrine; PaO_2, arterial partial pressure of oxygen.

[a] Catecholamine doses are expressed as mcg/kg/minute for at least 1 hour.

[b] GCS scores range from 3 to 15; higher score indicating better neurologic function.

Septic shock is characterized initially by a normal or high CO and a low SVR

(Table 17-3). Hypotension is caused by the low SVR and alterations in macrovascular and microvascular tone, which result in maldistribution of blood flow and volume. Changes in the microvasculature can lead to loss of normal microvascular autoregulatory mechanisms, resulting in constriction of capillaries, changes in cellular rheology, fibrin deposition, and neutrophil adherence. This causes vascular "sludging" and, in some cases, arteriovenous shunts that bypass capillary beds. Loss of intravascular fluid caused by increased vascular permeability and third spacing of fluid further adds to hypovolemia.[74] In an effort to compensate for the changes in volume and SVR, the body goes into a hyperdynamic state and increases CO. Most patients exhibit myocardial dysfunction as manifested by decreased myocardial compliance, reduced contractility, and ventricular dilation, but they maintain a normal CO because of tachycardia and cardiac dilatation which increases or maintains preload.[75] Although the cause of, and mechanism for, this abnormality is not fully understood, it is not believed to be attributable to myocardial ischemia. Rather, it is thought to be caused by one or more circulating inflammatory mediators, such as cytokines (e.g., interleukin-1), tumor necrosis factor-α (TNF-α), platelet-activating factor, arachidonic acid, nitric oxide (NO), and reactive oxygen species. In late septic shock, the body is no longer able to compensate because of the cardiac effects of the inflammatory mediators and resultant myocardial edema, thus resulting in a decreased CO. The end product of this complicated pathway is cellular ischemia, dysfunction, and eventually cellular death unless the chain of events is interrupted.

The complex pathogenesis of sepsis is more fully understood now, but some of the exact mechanisms are still not completely clear. The changes that take place during sepsis are caused by the immunologic host response to infection, which involves inflammatory (SIRS) and immunodepressive (compensatory anti-inflammatory response) mediators that are present from the onset of the immune response.[76]

The inflammatory stage of sepsis is initiated by an infection with a microorganism, most commonly bacterial. Organisms can either enter the bloodstream directly (producing positive blood cultures) or may indirectly elicit a systemic inflammatory response by locally releasing their toxins or structural components at the site of infection. The lipopolysaccharide endotoxin of gram-negative bacteria is the most potent soluble product of bacteria that can initiate a response and is the most studied, but other bacterial products can initiate the response, including exotoxins, enterotoxins, peptidoglycans, and lipoteichoic acid from gram-positive organisms. The binding of these toxins to cell receptors promotes proinflammatory cytokine production, primarily TNF-α and interleukin-1 (IL-1). These toxins stimulate the production and release of numerous endogenous mediators that are responsible for the inflammatory consequences of sepsis. The cytokines act synergistically to directly affect organ function and stimulate the release of other proinflammatory cytokines, such as IL-6, IL-8, platelet-activating factor, complement, thromboxanes, leukotrienes, prostaglandins, NO, and others.[75]

The presence of these cytokines promotes inflammation and vascular endothelial injury, but it also causes an overwhelming activation in coagulation. Thrombin has potent proinflammatory and procoagulant activities, and its production is increased in sepsis. The human body normally counteracts these effects by increasing fibrinolysis, but the homeostatic mechanisms in the septic patient are dysfunctional. There are decreases in the levels of protein C, plasminogen, and antithrombin III as well as increased activity of plasminogen activator inhibitor-1 and thrombin-activatable fibrinolysis inhibitor, endogenous agents that inhibit fibrinolysis.[76] The patient is in a coagulopathic state, which promotes formation of microvascular thrombi, leading to hypoperfusion, ischemia, and, ultimately, organ failure. Multiple organ failure is responsible for about half the deaths caused by septic shock.[77]

The clinical features of sepsis are highly variable and depend on multiple factors: site of infection, causative organism, degree of organ dysfunction, baseline patient health status, and delay to initial treatment.[78] The working definition of sepsis accounts for the presence of systemic manifestations of infection and organ dysfunction, which may be subtle (Table 17-8). Serum biomarkers are the subject of intense research as they could aid the early diagnosis of sepsis, guide treatment, and predict outcomes. Most biomarkers have not been extensively studied and few are in clinical use (e.g., C-reactive protein, procalcitonin, sTREM-1, CD64, pancreatic stone protein).[79] Most of these biomarkers have high negative predictive values, but lack high specificity and positive predictive value.

Characteristic laboratory findings include leukocytosis or leukopenia, thrombocytopenia with or without coagulation abnormalities, and, often, hyperbilirubinemia. These features are usually readily detectable and occur within 24 hours after bacteremia develops, particularly if gram-negative organisms cause the bacteremia. In extremes of age (very young or very old) or in debilitated patients, hypothermia can be present and positive findings may be limited to unexplained hypotension, mental confusion, and hyperventilation.

Persons dying of septic shock often have a normal or elevated CO. Death within the first week after the onset of sepsis occurs as a result of intractable hypotension that is secondary to significantly depressed SVR. This causes extensive maldistribution of blood flow in the microvasculature, with subsequent tissue hypoxia and development of lactic acidosis. Death occurring beyond the first week usually is caused by multiple organ failure that began during acute circulatory failure. Severe, unresponsive hypotension as a result of a decreased CO occurs in a subpopulation of patients with septic shock; cardiogenic shock becomes superimposed on the distributive shock of sepsis, but this is a less common cause of death.[80]

Clinical and Hemodynamic Features

CASE 17-4

QUESTION 1: E.B., a 71-year-old woman, presents to the ED from a skilled nursing facility with a several day history of low-grade fever, rigors, and chills. She does not report a history of nausea or vomiting but had exceedingly poor oral intake for several days prior to admission.

E.B. has a history of diabetes mellitus type 2, hypertension, chronic kidney disease stage II, dyslipidemia, coronary artery disease, obesity, and peripheral arterial disease. She has a history of a transient ischemic attack and right lower extremity below-the-knee amputation.

Physical findings include a temperature of 38.7°C, BP 95/60 mm Hg, pulse 120 beats/minute, and RR 28 breaths/minute with oxygen saturation 95% on 2 L/minute nasal cannula. E.B. weighs 102 kg and is 65 inches tall. A Foley catheter is placed in her bladder and her urine output is 0.4 mL/kg/hour. The chest radiograph shows an enlarged heart, low lung volumes, and a distended, gas-filled stomach but no focal airspace disease, pneumothorax, or pleural effusion. Her left lower extremity has foul-smelling, purulent drainage from the posterior heel, surrounding erythema with macerated areas, and the heel is tender to the touch. E.B. has 3+ edema in the foot and lower extremity but no other significant findings aside from the heel ulcer. The patient also has a large stage III sacral decubitus ulcer with several open wound areas and serosanguinous drainage.

Pertinent laboratory values are as follows:

WBC count, 19,500 cells/µL
BUN, 58 mg/dL
SCr, 2.2 mg/dL
Na, 131 mEq/L
Glucose, 58 mg/dL
Albumin, 1.6 g/dL
ABG measurements on 2 L/minute nasal cannula (FiO_2 27%) are as follows:
PaO_2, 98 mm Hg
$PaCO_2$, 32 mm Hg
HCO_3^-, 16 mEq/L
pH, 7.31

Urine, sputum, blood, and deep tissue wound samples are sent for culture and sensitivity. A fluid bolus of 1,000 mL of normal saline solution is given. Arterial and pulmonary artery catheters are inserted, revealing the following hemodynamic profile:

BP (S/D/M), 90/48/62 mm Hg
HR, 122 beats/minute
CO, 7.1 L/minute
CI, 3.4 L/minute/m^2
PCWP, 10 mm Hg
SVR, 720 $\text{dyne}\cdot\text{s}\cdot\text{cm}^{-5}$

What hemodynamic and clinical features of E.B. are consistent with septic shock?

E.B. would not be classified in septic shock at this time because she has not been adequately fluid resuscitated. Though, she would be classified as having sepsis because of the manifestations of infection and organ dysfunction.

Hemodynamic signs consistent with sepsis include hypotension, tachycardia, elevated CO, low SVR, and low PCWP. Although the absolute value for CO is high or at the upper limits of the normal range, in septic shock it is inadequate to maintain a BP that will perfuse the essential organs in the face of a decreased SVR, evidenced by a low $\dot{D}O_2$ and $\dot{V}O_2$. E.B. has a metabolic acidosis (pH 7.31, $Pa\textsc{co}_2$ 32 mm Hg, HCO_3^- 16 mEq/L), indicating anaerobic metabolism and lactic acidosis most likely caused by decreased perfusion, and a CO that is inadequate to meet the oxygen requirements of the tissues.

Other features consistent with sepsis in E.B. include declining urine output indicating decreased renal perfusion, hypoglycemia, a rising WBC count, and a spiking fever.

Therapeutic Approach

The management of septic shock is directed toward three primary areas: (a) eradication of the source of infection, (b) hemodynamic support and control of tissue hypoxia, and (c) inhibition or attenuation of the initiators and mediators of sepsis.

ERADICATING THE SOURCE OF INFECTION

CASE 17-4, QUESTION 2: What factors should be considered in determining antimicrobial therapy in septic shock? What are the potential sources of infection in E.B.?

Systemic infection caused by either aerobic or anaerobic bacteria is the leading cause of septic shock. Fungal, mycobacterial, rickettsial, protozoal, or viral infections can also be encountered. Among sepsis syndromes caused by aerobic bacteria, gram-negative organisms (e.g., Pseudomonas, Enterobacteriaceae, and Acinetobacter, in decreasing order of frequency) are implicated slightly more often than gram-positive bacteria (e.g., Staphylococcus aureus, Enterococcus, Staphylococcus epidermidis, and Streptococcus, from highest to lowest frequency). Even these trends vary, however, depending on the infection site. For example, when an organism can actually be cultured in the blood, slightly more gram-positive infections (35% to 40%) than gram-negative infections (30% to 35%) are found. In non-bloodstream infections (e.g., respiratory tract, genitourinary system, and the abdomen, in descending order of frequency) 40% to 45% can be attributed to gram-negative

---

organisms, and 20% to 25% are caused by gram-positive organisms.[71] Polymicrobial infections make up the next largest group, followed by fungi, anaerobes, and others. In up to 33% of sepsis syndrome cases, no organisms can be isolated. Careful consideration of the patient's history and clinical presentation often reveals the most likely cause.

Eradicating the source of infection involves the early administration of antimicrobial therapy, and, if indicated, surgical drainage. The use of an appropriate antibiotic regimen within 1 hour of the diagnosis of sepsis or septic shock is associated with a significant increase in survival. Appropriate cultures should be obtained before starting antibiotic therapy, unless this would result in a significant (greater than 45 minutes) delay in therapy.[4] The selection of antibiotics should take into account the presumed site of infection; whether the infection is community- or health care-associated; recent invasive procedures, manipulations, or surgery; any predisposing conditions; drug intolerances; and the likelihood of drug resistance. Ideally, the primary source of infection can be determined and therapy specifically tailored to the most likely organisms. If the source of infection is unclear, however, early institution of broad-spectrum antibiotics against all likely pathogens is generally recommended while awaiting culture results. Empiric broad-spectrum therapy usually requires combinations of antimicrobials because of the increasing frequency of polymicrobial infections and antimicrobial resistance. Even so, there are no data demonstrating better outcomes with combination therapy over adequate monotherapy, except in severely ill, septic patients with a high risk of death.[4,78] Empiric regimens must be determined by patient factors and broad enough to cover all likely pathogens. Mortality for septic shock may be as much as fivefold higher when an empiric regimen fails to cover the offending pathogen.[4] Because a wide range of variables must be considered in the selection of empiric regimens (e.g., anatomic site of infection, pathogen prevalence, resistance patterns), a specific regimen cannot be recommended for all episodes of sepsis or septic shock (see Chapter 62, Principles of Infectious Diseases). Generally, empiric regimens target gram-positive cocci, aerobic gram-negative bacilli, as well as anaerobes and include (1) an anti-pseudomonal penicillin, third- or fourth-generation cephalosporin, or carbapenem plus (2) vancomycin to cover methicillin-resistant Staphylococcus aureus. Combination gram-negative coverage (e.g., aminoglycoside, fluoroquinolone) is recommended for critically ill patients at risk of infection with difficult-to-treat, multidrug-resistant pathogens, such as Pseudomonas and Acinetobacter spp. Additional coverage should be considered based on the presence of other risk factors (e.g., Candida species, atypical pathogens).

Individuals with diabetes are presumed to be at an increased risk of infection because of multiple host factors, including hyperglycemia-induced immunosuppression, vascular insufficiency, peripheral neuropathies, and colonization with S. aureus and Candida species. The most likely potential sources of sepsis in E.B. are a combination of skin and soft tissue infections. E.B. has a severe diabetic foot infection involving her left heel with inflammation, purulence, and systemic manifestations of infection. She also has a large stage III sacral decubitus ulcer. A urinary tract infection and vulvovaginal candidiasis should be considered as well because of her history of diabetes. Other sources of infection are less likely based on her presentation. All IV catheters from the skilled nursing facility should be changed if possible.

Infected pressure ulcers and diabetic foot infections are usually polymicrobial wounds. These infections should be treated with parenteral broad-spectrum antibiotics to cover methicillin-sensitive and methicillin-resistant S. aureus, Streptococcus spp., Enterobacteriaceae, Pseudomonas aeruginosa, and obligate anaerobes (e.g., Peptostreptococcus, Peptococcus, Bacteroides fragilis, and Clostridium perfringens). As such, empiric therapy should include vancomycin in combination with one of the following: piperacillin–tazobactam, ceftazidime, ceftaroline, cefepime, aztreonam, or a carbapenem. If aztreonam or a cephalosporin is chosen then metronidazole or clindamycin should be considered to cover anaerobic organisms, particularly for ischemic or necrotic wounds.[81,82] Drainage, debridement, and wound dressing should accompany antibiotic therapy. Antimicrobial therapy should be adjusted once cultures are finalized.

INITIAL STABILIZATION

CASE 17-4, QUESTION 3: What are the immediate goals of therapy in E.B.? How can they be achieved and assessed?

The goals in treating septic shock, in addition to eradicating the precipitating infection, are to optimize $\dot{D}O_2$ to the tissues and to control abnormal use of oxygen and anaerobic metabolism by reducing the tissue oxygen demand. Tissue injury is widespread during sepsis, most likely because of vascular endothelial injury with fluid extravasation and microthromboses, which decrease oxygen and substrate utilization by the affected tissues. The mainstay of therapy is volume expansion to increase intravascular volume, enhance CO, and ultimately delay associated development of refractory tissue hypoxia.

Increasing CO with fluids will improve capillary circulation and tissue oxygenation by maintaining sufficient intravascular volume. At least 30 mL/kg of IV crystalloid fluid should be given within the first 3 hours of resuscitation.[4] If fluids do not correct the hypoxia or if filling pressures are increased, the sequential addition of vasopressors and inotropic agents is indicated. Blood transfusions should be used if the Hgb is less than 7 g/dL unless there is an active source of bleeding, severe hypoxemia, or a history of cardiac disease, in which case the Hgb value would be maintained at a higher value.[4] Crystalloids (with electrolytes to correct imbalances) should be initiated to maintain the CI goal as well as a MAP of 65 mm Hg. Although MAP is not an absolute measure of blood flow to all vital organs, it is considered the therapeutic end point that will sustain myocardial and cerebral perfusion. A higher MAP could be considered in septic patients with a history of hypertension or those who clinically improve with a higher BP.[1] After optimization with fluid therapy, vasopressor and inotropic agents are indicated if the patient remains hypotensive with a low CI or if signs of inadequate tissue perfusion persist.

The therapeutic goals used for hemodynamic resuscitation are controversial. The issue is whether therapy should be directed to physiologic end points of tissue perfusion or clinical end points, such as BP and urine output. The physiologic end points include clearance of blood lactate concentrations, base deficit, Svo_2, and increased CO. Serum lactate concentrations may be elevated through various mechanisms (e.g., tissue hypoxia, excessive beta-adrenergic stimulation, liver failure) but are associated with worse outcomes regardless of the source. Lactate-guided resuscitation of patients in septic shock is recommended because of its association with a significantly reduced mortality rate compared with usual care.[4]

Many institutions have developed "sepsis bundles" that incorporate these same variables and therapeutic end points as early as possible in the treatment of sepsis. Sepsis bundles often include many additional issues addressed in the Surviving Sepsis Campaign Guidelines,[4] such as ventilatory support, initial choice of antibiotics, glucose control, and stress ulcer prophylaxis.

One study by Rivers et al. combined physiologic and clinical end points of resuscitation during the early stages of sepsis.[83] CVP, MAP, Hct, and $ScvO_2$ were optimized during at least 6 hours of continuous care in the ED. This was compared to conventional therapy that targeted only CVP, MAP, and urine output. In-hospital mortality was significantly lower in the early goal-directed therapy

---

(EGDT) group (30.5% vs. 46.5%, p = 0.009). EGDT was adopted as the standard of care in the treatment of sepsis and septic shock. However, there are several limitations to the EGDT approach. As noted above, CVP is an unpredictable marker of fluid resuscitation,[38] and fluid overload is common after EGDT resuscitation. Furthermore, the Hct target of 30% is unnecessarily high because transfusions of PRBCs to achieve a Hgb above 7 g/dL do not increase $Scvo_2$. Finally, dobutamine could also be harmful if used to increase $Scvo_2$ in patients with unevaluated ventricular function.[84]

Several large, multicenter studies have shown no improvement in patient outcomes using EGDT for severe sepsis and septic shock. Protocol-based resuscitation did not improve in-hospital mortality among 1,341 patients in the ProCESS study.[85] In the ARISE and ProMISe studies, EGDT did not reduce all-cause mortality compared to usual care.[86,87] The mortality rates among the usual care groups from these trials (18.9%,[85] 18.8%,[86] 29.2%[87]) were similar to the EGDT group in the Rivers et al. study. These findings could be because of an improvement in our standard of care over that time period, chiefly the early identification and treatment. Nonetheless, the most recent Surviving Sepsis Campaign Guidelines[4] have departed from the EGDT-guided resuscitation strategy from the Rivers study.

E.B. should receive fluid boluses to maintain perfusion with a MAP of at least 65 mm Hg. Reassessment of E.B.'s hemodynamic status should include a thorough clinical examination as well as assessment of available physiologic variables (e.g., HR, BP, SaO_2, RR, temperature, urine output) and measurements from her PA catheter. A minimum of 30 mL/kg crystalloid fluid challenge is recommended within the first 3 hours of resuscitation. Albumin may be substituted if large volumes of crystalloids are required, but hydroxyethyl starches should be avoided because of an increased risk of acute renal dysfunction and potential increased mortality.[4] Continued, excessive fluid challenges to increase preload in E.B. must be approached cautiously because she has an enlarged heart on chest radiograph, coronary artery disease, and multiple risk factors for heart failure. In addition, patients in septic shock are susceptible to experiencing non-cardiogenic pulmonary edema or ARDS, which can cause severe deterioration in pulmonary function. Fluid boluses should be given with ongoing monitoring to determine the CVP and PCWP at which CO is maximal. This approach will avoid excessive CVP and PCWP beyond which CO is no longer increased, reducing potential pulmonary edema.

In summary, the immediate goal of therapy is to maximize $\dot{D}O_2$ to the tissues. Fluid resuscitation is the mainstay of therapy and improves $\dot{D}O_2$ by increasing CO; however, inotropic and vasopressor agents are often required for additional cardiovascular support. A favorable response to immediate resuscitative efforts will be reflected by a reversal or halt in the progression of the metabolic acidosis, improved sensorium, and increased urine output. In E.B., surgical evaluation and debridement and selection of appropriate antibiotics while maintaining hemodynamic support are the clinical goals of therapy.

HEMODYNAMIC MANAGEMENT

Fluid Therapy Versus Inotropic Support

CASE 17-4, QUESTION 4: E.B. is given three 1,000-mL fluid boluses, and norepinephrine is begun at a rate of 0.05 mcg/kg/minute. During the next 2 hours, she receives 4 L of fluid in boluses, and the norepinephrine is increased to 0.3 mcg/kg/minute to maintain her BP. She does not have signs of pulmonary edema. E.B. has the following hemodynamic profile (previous values in parentheses):

BP (S/D/M), 95/48/64 mm Hg (90/48/62 mm Hg)
HR, 124 beats/minute (122 beats/minute)
CO, 8 L/minute (7.1 L/minute)
CI, 3.8 L/minute/m^2 (3.4 L/minute/m^2)
CVP, 12 mm Hg (7 mm Hg)
PCWP, 16 mm Hg (10 mm Hg)
SVR, 550 $dyne\cdot s\cdot cm^{-5}$ (720 $dyne\cdot s\cdot cm^{-5}$)
Urine output, 0.25 mL/kg/hour (0.4 mL/kg/hour)
PaO_2, 85 mm Hg (98 mm Hg)
$PaCO_2$, 36 mm Hg (32 mm Hg)
HCO_3^-, 17 mEq/L (16 mEq/L)
pH, 7.3 (7.31)
$\dot{D}O_2$, 534 mL/minute (508 mL/minute)
$\dot{V}O_2$, 198 mL/minute (324 mL/minute)

Which of the following therapeutic considerations would be reasonable for E.B. at this time: additional fluid boluses, an increase in the norepinephrine infusion rate, or initiation of a different vasopressor?

E.B. continues to be hypotensive despite a PCWP of 16 mm Hg and a norepinephrine infusion rate of 0.3 mcg/kg/minute. The goals of therapy remain the same (i.e., maximize arterial oxygen content and $\dot{D}O_2$ to reverse cellular anaerobic metabolism).

E.B.'s PaO_2 of 85 mm Hg correlates with an oxygen–hemoglobin saturation of approximately 96%, which should provide an adequate arterial oxygen content. However, $\dot{D}O_2$ still may be inadequate despite the CI being above 3.5 L/minute/m^2 because $\dot{D}O_2$ and $\dot{V}O_2$ have not reached normal levels. E.B.'s Hgb and Hct should be checked to ensure adequate oxygen-carrying capacity in the blood. In addition, decreased tissue oxygen utilization can contribute to the continued acidosis. Further attempts to enhance the CI and, hence, $\dot{D}O_2$ are appropriate. E.B. has a dilated heart and a history of cardiovascular disease and chronic kidney disease that will influence the choice of therapeutic options.

Although fluid administration is the mainstay of therapy in septic shock, the elevation of E.B.'s PCWP to 16 mm Hg without a significant increase in CO suggests that an optimal PCWP has been reached. Therefore, additional fluid therapy to maintain BP may cause pulmonary edema and compromise pulmonary gas exchange. A plot of CO versus PCWP (ventricular function curve) would provide a more accurate assessment of the PCWP at which CO is maximal. Additional fluid boluses at this time should be used only to maintain the current level of intravascular volume status.

VASOPRESSORS AND INOTROPIC AGENTS

When fluid therapy fails to maintain a satisfactory MAP despite an elevated CO, the use of a vasopressor should be considered. Maintaining a goal MAP does not correlate with decreased mortality, but it helps sustain myocardial and cerebral perfusion. If it is necessary to increase CO, then inotropic agents should be used. Although the use of inotropic agents is well established, controlled comparative studies have not clearly determined which agent, or combination of agents, is most useful in the management of septic shock. Because differences among the inotropic agents are significant, however, selection of the most appropriate drug should be guided by careful consideration of the patient's hemodynamic status.

Norepinephrine and Dopamine

Norepinephrine is predominantly an α-adrenergic agonist (Table 17-7) and is the recommended first-line vasopressor for sepsis.[4] Norepinephrine has been titrated to 0.3 mcg/kg/min, but E.B.'s HR will likely limit the utility of further increases in the dose.

Dopamine has frequently been another initial pharmacologic agent chosen for the treatment of septic shock. A trial that randomized 1,679 patients with shock to dopamine or norepinephrine for BP support found no significant difference in the primary outcome of 28-day mortality but an increased risk of arrhythmic events with dopamine.[60] A meta-analysis of six randomized trials of septic patients found dopamine was associated with an increased risk of death and arrhythmias compared to norepinephrine.[88] Similarly, another meta-analysis that included six randomized trials found norepinephrine was associated with a lower in-hospital and 28-day mortality compared to dopamine as well as a lower incidence of arrhythmias.[89]

In light of these findings, the Surviving Sepsis Campaign relegated dopamine from a first-line to alternative vasopressor. Dopamine is now reserved for patients with absolute or relative bradycardia and a low risk of tachyarrhythmias, which is difficult to predict.[4] Accordingly, dopamine is not an appropriate therapeutic option for E.B.

Low-dose dopamine should not be used for renal protective purposes.[4] Despite the improvement in renal blood flow and a possible increase in urine output, dopamine does not decrease the time to recovery of renal function or the need for renal replacement therapy.

Epinephrine

Epinephrine stimulates α-, β_1-, and β_2-adrenergic receptors (Table 17-7). CO is augmented via increased contractility and HR, with the contribution of each being highly variable. Blood vessels in the kidney, skin, and mucosa constrict in response to α-adrenergic stimulation, whereas vessels in the skeletal muscle vasodilate because of β_2 effects. A biphasic response in SVR is observed as β_2-receptors are activated at the lower range and α_1-receptors are stimulated at higher infusion rates. The improvement in CO, therefore, may be negated by an increase in afterload at higher dosages.

Historically, epinephrine was reserved as a last-line therapy because of the studies that showed harmful splanchnic and renal vasculature effects and elevated lactate levels. Despite these effects, there are no clinical studies showing that epinephrine causes worse outcomes in sepsis. In fact, two prospective, double-blind, randomized controlled trials comparing epinephrine and norepinephrine in patients with septic shock found similar mortality rates, time to hemodynamic recovery, and time to vasopressor withdrawal.[90,91] Both studies showed lower arterial pH values associated with impaired serum lactate clearance in the epinephrine-treated groups. Therefore, lactate clearance would not be recommended to guide resuscitation when utilizing epinephrine.

Epinephrine is recommended as adjunctive therapy to norepinephrine to maintain adequate MAP.[4] However, if tachyarrhythmias are limiting the use or norepinephrine, epinephrine is likely to produce similar effects because it also stimulates β_1-receptors. Consequently, it is not appropriate to substitute epinephrine for norepinephrine at this time for E.B.

Vasopressin

Catecholamines have been the mainstay of treatment to support BP in septic patients once adequate fluid resuscitation has been achieved. Sepsis, however, can cause a decrease in responsiveness to catecholamines, resulting in refractory hypotension, possibly because of down-regulation of adrenergic receptors or altered receptor relative binding affinities in hypoxic and acidotic conditions.[59] Vasopressin is an endogenous hormone that has very little effect on BP under normal conditions, but it becomes important in maintaining BP when the baroreceptor reflex is impaired. In contrast to the catecholamines, vasopressin's effects are relatively preserved in hypoxic and acidotic states.[59]

Vasopressin's direct vasoconstricting actions are mediated by the vascular V_{1a} receptors coupled to phospholipase C.[59,92] When these receptors are activated, calcium is released from the sarcoplasmic reticulum in smooth muscle cells, leading to vasoconstriction. Vasopressin levels peak in early septic shock and decrease to low-normal levels in most patients within 48 hours. This phenomenon is coined a "relative vasopressin deficiency" because higher vasopressin levels would be expected in hypotensive states.

The VASST study compared norepinephrine to vasopressin in patients with septic shock, who were unresponsive to fluids and assessed mortality at 28 days.[93] Vasopressin 0.01 to 0.03 units/minute added to norepinephrine was compared to norepinephrine monotherapy. Vasopressin significantly decreased the amount of norepinephrine required; however, there was no difference in mortality between the treatment groups except when the patients were stratified according to severity of sepsis. The patients with less severe septic shock benefited from vasopressin therapy. This study evaluated vasopressin as a catecholamine-sparing drug rather than as rescue therapy for catecholamine-unresponsive shock, which was how it was studied in previous trials.

Small studies have shown vasopressin to be as effective as catecholamines in achieving blood pressure control with no difference in mortality, but vasopressin is not recommended as first-line therapy because of a delayed physiologic response.[4,92] Instead, low-dose vasopressin (up to 0.03 units/minute) is recommended to synergistically achieve the goal MAP with norepinephrine or allow norepinephrine dose reductions.[4] Doses higher than 0.03 to 0.04 units/minute are only recommended as salvage therapy.[4]

E.B. has a decreased MAP despite the increased titration of norepinephrine. The optimal time to consider additional or alternative therapies to norepinephrine is unknown. Because patients in septic shock have decreased endogenous levels of vasopressin, it would be reasonable to add vasopressin at 0.03 units/minute to increase the MAP and renal perfusion.

Phenylephrine

Phenylephrine is a pure α-adrenergic agonist (Table 17-7) and, thus, increases systolic, diastolic, and mean arterial pressures through vasoconstriction. Reflex bradycardia can occur secondarily because of the absence of β-adrenergic effects. The increase in afterload, while increasing myocardial $\dot{V}O_2$, correspondingly increases coronary blood flow because of increased perfusion pressure and autoregulation. In patients with myocardial hypoxia, or in those experiencing atrial or ventricular arrhythmias, phenylephrine can be beneficial because it has minimal direct cardiac effects. In situations in which the CO is decreased, phenylephrine can be detrimental. Preload is reduced as plasma fluid is lost owing to increased capillary hydrostatic pressure, forcing water and solutes from the vascular space into the interstitial spaces. This response, in addition to the increased afterload and reflex bradycardia, may significantly impair CO (Table 17-7). Therefore, phenylephrine should be reserved for treating septic shock in the following patients: (a) those with arrhythmias on norepinephrine, (b) those with high CO but persistent hypotension, or (c) those who fail to achieve the goal MAP on combination inotropes/vasopressors and low-dose vasopressin. Phenylephrine is a reasonable alternative therapy for E.B. if her hypotension and tachycardia persist despite the addition of vasopressin.

Dobutamine

Tissue $\dot{D}O_2$ may be impaired by a suboptimal CO or decreased oxygen-carrying capacity. If tissue hypoperfusion persists after optimizing fluid status, achieving the goal MAP, and assuring an adequate Hgb concentration, then CO should be assessed. Epinephrine and dopamine are inotropic therapies with vasoconstricting properties, but dobutamine is the recommended first-line inotropic agent in the management of septic shock.[4] Dobutamine

produces a greater increase in CO than dopamine, but it also lowers SVR. In contrast to dopamine, dobutamine lowers PCWP and causes less pulmonary shunting. Because dobutamine can lower ventricular filling pressure, volume status must be monitored closely to avoid the development of hypotension and reduced MAP. Fluids should be administered as needed to maintain the PCWP at optimal and tolerated levels of 15 to 18 mm Hg. With the administration of greater amounts of fluid, CO, $\dot{D}O_2$, and systemic $\dot{V}O_2$ are significantly increased. Dobutamine increases $\dot{D}O_2$ and CI when given concurrently with or after volume resuscitation, and it may independently increase capillary perfusion regardless of systemic effects.[51] Decreases in PaO_2 and increases in venous PO_2, as well as adverse effects on myocardium, may be evident at higher dosages (above 6 mcg/kg/minute).[94]

Combinations of vasopressors and inotropic agents can also be used to achieve desired hemodynamic parameters. GI perfusion can be compromised owing to the vasoconstricting effects of catecholamines and may play a role in the pathogenesis of multiple organ dysfunction.[65] Currently, it is unknown whether a specific catecholamine regimen provides a significant benefit over others. There are conflicting data about which vasopressor can increase gastric perfusion and whether this increase can alter progression to organ dysfunction.

CASE 17-4, QUESTION 5: Given E.B.'s history of cardiovascular disease, what factors should you consider before initiating an inotropic or alternative vasopressor agent? Outline an overall approach to maintaining adequate hemodynamic status.

E.B. has a history of coronary artery disease and is susceptible to myocardial ischemia. Therefore, a careful balance must be achieved between myocardial $\dot{V}O_2$ and coronary perfusion pressure. Further attempts to optimize MAP and CI with norepinephrine alone could increase myocardial $\dot{V}O_2$ and precipitate ischemia. Evidence suggests that the goal of therapy in treating patients with septic shock, or any form of shock for that matter, is not to simply normalize BP but to optimize $\dot{D}O_2$ and $\dot{V}O_2$. Once anemia and hypoxia have been corrected, CO becomes the remaining parameter that can be adjusted to increase oxygen supply, but raising arterial BP and CO with inotropic agents or vasopressors before restoring adequate blood volume can actually worsen tissue perfusion. Therefore, the patient's current hemodynamic status and the individual properties of those agents that will most effectively maintain or increase the MAP and CO should be considered while selecting an inotropic agent. In many instances, because of individual variability and response, more than one inotropic agent or addition of a vasopressor is required to achieve these end points. These interventions must be made with strict monitoring of the patients' response to the interventions to prevent any adverse consequences, especially in those patients who are predisposed to an adverse event, such as E.B.

It is important to realize that the response to exogenous catecholamines in patients with septic shock is highly variable and a successful regimen in one patient may be unsuccessful in another. In addition, septic patients often require infusion rates in the moderate-to-high range. Therefore, the goal is to use one or more agents at the dosages necessary to achieve the desired end points without unduly compromising the patient's status. The use of catecholamines, however, is only a stabilizing measure. Strict attention to all other physiologic parameters—as well as nutritional support, antibiotic modification, respiratory support, and ongoing surgical intervention—cannot be overemphasized.

OTHER THERAPIES

Therapies directed against the initiators and mediators of sepsis are currently the focus of intense investigation. Numerous exogenous and endogenous substances are involved in the pathogenesis of sepsis within the cytokine and coagulation cascades. Strategies under development include antioxidants and free radical scavengers; anti-endotoxin therapy; and inhibition of leukocytes, secondary mediators (i.e., TNF-α, IL-1, cytokine pathway), coagulation and arachidonic acid metabolites, complement, and NO. The lack of development of successful new therapies over the past two decades is probably because of multiple factors, such as poor clinical trial design, oversimplification of the pathologic process in animal models, and suboptimal patient selection criteria.[79] Although several experimental therapies hold promise for the future, controlled human trials are still lacking.

Corticosteroids

CASE 17-4, QUESTION 6: What is the rationale for the use of glucocorticoids in the treatment of septic shock, and is there evidence to support their use for this indication in E.B.?

The use of corticosteroids in sepsis and septic shock has been a controversial topic for many years. Corticosteroids were originally proposed as a treatment option because of their anti-inflammatory properties with the hope of attenuating the body's response to infection. It has been shown that critically ill patients exhibit impaired cortisol secretion because of a relative adrenocortical insufficiency and a glucocorticoid peripheral resistance syndrome that can also be affected by multiple medications.[95] The Consensus Task Force from the American College of Critical Care Medicine has defined this dysfunction of the hypothalamic–pituitary–adrenal axis as critical illness–related corticosteroid insufficiency.[96]

Diagnosis of this condition is intensely debated. Some clinicians recommend a random cortisol level that is below a certain threshold during physiologic stress (i.e., shock) to diagnose adrenal insufficiency; however, this has only been shown to be useful in diagnosing absolute adrenal insufficiency.[4] The traditional assessment method has been the adrenal corticotropin hormone (ACTH) stimulation test with administration of either 1 mcg or 250 mcg of cosyntropin. Though, the ACTH tests only evaluates the adrenal function, not the entire hypothalamic–pituitary–adrenal axis, and lacks sensitivity and specificity in critical illness.[95] Random cortisol levels may be useful for evaluating absolute adrenal insufficiency but have not demonstrated a benefit in septic shock patients. The Surviving Sepsis Campaign does not recommend the ACTH stimulation test or random cortisol levels to identify patients who should receive glucocorticoids.[4]

Clinical trials investigating the use of steroids in septic shock have been performed with varying results. The trial by Annane et al.[97] showed a shortened time to shock reversal and mortality benefit with the use of low doses of hydrocortisone and fludrocortisone in patients with severe septic shock, who exhibited a relative adrenocortical insufficiency (serum cortisol increase less than or equal to 9 mcg/dL in response to ACTH stimulation). The CORTICUS trial[98] showed a faster resolution of shock for those patients on hydrocortisone as evidenced by faster time to weaning from vasopressors; however, those patients also had a higher incidence of superinfection and new episodes of sepsis or septic shock. There was no mortality benefit seen with the use of corticosteroids. The CORTICUS trial included patients with septic shock, whereas the study by Annane et al. only enrolled patients with severe septic shock unresponsive to vasopressor therapy. A recent retrospective study in patients with septic shock noted a neutral effect with corticosteroids, but a subgroup analysis revealed a 30-day mortality benefit in the patients with the highest severity of illness.[99] Additionally, refractory patients who have progressed to vasopressin therapy may have an even greater benefit. In a post hoc analysis of the VAAST trial, treatment with corticosteroids and

---

vasopressin was associated with decreased organ dysfunction and mortality compared with corticosteroids and norepinephrine.[100] The results of these studies demonstrate that corticosteroid therapy may not have a role in the general population of patients with septic shock; however, it may be beneficial for those patients unresponsive to vasopressors who are treated early.

The optimal dose, duration, and method of administration are still unknown. The Surviving Sepsis Campaign recommends hydrocortisone 200 mg/day.[4] Continuous infusion of hydrocortisone may avoid significant fluctuations in glucose and sodium. Because E.B. is refractory to increasing doses of norepinephrine and is in severe sepsis, it was decided to start hydrocortisone 50 mg IV every 6 hours.

Statins

CASE 17-4, QUESTION 7: Should E.B. be started on a statin? Are there any differences in outcomes for patients taking statin therapy prior to developing sepsis?

Aside from their well-described lipid-lowering effects, statins appear to have immunomodulatory and anti-inflammatory effects. Statin therapy lowers C-reactive protein levels, inhibits endothelial cell dysfunction, causes up-regulation of endothelial NO synthase, and blocks immune cell receptors.[101] A recent meta-analysis of seven randomized, controlled trials comprising 1,720 septic patients did not show a decrease in mortality outcomes compared to placebo, regardless of the type of statin, dose, or observed mortality rates.[102] Statins are often discontinued in septic patients because of concern for adverse effects and further organ dysfunction. Presently, it is not clear whether statins should always be continued in septic patients. Recent studies in patients who were taking statin therapy prior to sepsis have not shown any difference in outcomes or rebound inflammation when discontinuing therapy.[103,104] More prospective, randomized trials are needed to further define the role of statins in sepsis.

DISSEMINATED INTRAVASCULAR COAGULATION

Pathophysiology

CASE 17-4, QUESTION 8: E.B. experiences sudden appearance of bright red blood per rectum and through her nasogastric tube; thus, a coagulation screen was ordered. Until this time, all coagulation parameters had been within normal limits. Now the results show the following:

Platelets, 43,000/μL
PT, 24 seconds
Activated PTT, 76 seconds
Thrombin time, 48 seconds (normal, 16–27 seconds)
Fibrinogen, 60 mg/dL
Fibrin degradation products, 580 ng/mL (normal, less than 250 ng/mL)

The diagnosis of disseminated intravascular coagulation (DIC) is made. How does the pathophysiology of DIC explain these hematologic abnormalities?

Thrombosis in response to endothelial damage or the presence of an altered surface in contact with blood components is a localized phenomenon. Thrombus formation occurs at the site of injury or abnormality, where procoagulant and anticoagulant mechanisms, as well as fibrinolytic and antifibrinolytic mechanisms, are regulated. The term localized extravascular coagulation describes the site-specific nature of venous and arterial thrombosis.

In contrast, DIC is a diffuse response secondary to an underlying disorder that causes systemic activation of the coagulation system (Fig. 17-5).[105] Circulating thrombin converts fibrinogen to fibrin, resulting in fibrin deposition within the microcirculation. Clinical manifestations of microvascular thrombosis are the result of tissue ischemia resulting from thrombotic occlusion of small and midsize vessels.

The presence of systemic circulating thrombin causes simultaneous systemic activation of the fibrinolytic system, resulting in circulating plasmin within the systemic circulation. Plasmin causes systemic lysis of fibrin to fibrin degradation products and results in hemorrhagic complications.

Bleeding manifestations of DIC occur not only as a result of systemic fibrinolysis but also secondary to thrombocytopenia, clotting factor deficiency, and platelet dysfunction. Circulating thrombin promotes platelet aggregation, resulting in thrombocytopenia as platelet aggregates deposit in the microcirculation. Circulating plasmin degrades clotting factors as well as fibrin, and the presence of fibrinogen degradation products from fibrinolysis inhibits platelet function. Normal mechanisms of platelet and clotting factor synthesis are unable to compensate for this consumption. In essence, the patient shows paradoxical bleeding secondary to overactivation and eventual consumption of available clotting factors and platelets.

Formation of Fibrin Degradation Products
Platelet Dysfunction
Hemorrhage
Microvascular Thrombosis

Figure 17-5 Pathophysiology of disseminated intravascular coagulation.

Precipitating Events

CASE 17-4, QUESTION 9: What events may have precipitated the development of DIC in E.B.?

DIC is a pathologic syndrome triggered by disease states or conditions that activate coagulation systemically rather than locally.[105] The presence of thrombin within the systemic circulation can be triggered by systemic endothelial damage (e.g., bacterial endotoxin), systemic contact activation of the clotting cascade (e.g., cardiopulmonary bypass), or the release of procoagulants into the systemic circulation (e.g., malignancy). Table 17-10 presents an abbreviated list of disorders associated with the development of DIC. DIC complicates approximately 35% of severe sepsis cases.[105] Although sepsis is the most likely stimulus for DIC in E.B., both hypoxia and acidosis associated with respiratory compromise may also have contributed. Importantly, the development of DIC in septic patients has been shown to be an independent predictor of mortality.[76]

Clinical Presentation

CASE 17-4, QUESTION 10: What subjective and objective evidence in E.B. is consistent with the diagnosis of acute DIC?

LABORATORY FINDINGS

Many coagulation laboratory abnormalities occur in DIC.[105,106] The ratio of PT to international normalized ratio, the activated PTT, and the thrombin time are increased because clotting factors, as well as antithrombin and proteins C and S, are consumed more quickly than they can be replenished by hepatic synthesis. Platelet count is diminished secondary to thrombin-mediated platelet aggregation. Fibrinogen is reduced as a result of plasmin-mediated fibrinolysis, with an elevation in fibrinogen degradation products including D-dimer, indicative of a fibrinolytic state. A peripheral smear will often show thrombocytopenia and red blood cells fragmented by exposure to microcirculatory fibrin (schistocytes).

The International Society of Thrombosis and Haemostasis Overt DIC Scoring System is used in the diagnosis of DIC (Table 17-11).[107] The sensitivity and specificity of the DIC score is 93% and 98%, respectively.[108,109] There is a strong correlation between increasing DIC score and 28-day mortality.[108]

HEMORRHAGIC MANIFESTATIONS

As illustrated by E.B., hemorrhagic manifestations are the predominant clinical finding in DIC.[105] Bleeding can occur at sites of injury, including surgical incisions, venipuncture sites, nasogastric tubes, or gastric ulcers. However, spontaneous bleeding also occurs from intact sites or organ systems. Spontaneous ecchymosis, petechiae, epistaxis, hemoptysis, hematuria, and GI bleeding are commonly encountered. Intracranial, intraperitoneal, and pericardial bleeding may also occur. Critically ill patients with platelet counts less than 50,000/μL have a fourfold to fivefold higher risk of bleeding, but major bleeding occurs in a minority of patients.[105]

THROMBOTIC MANIFESTATIONS

Thrombotic manifestations of DIC result in the obstruction of blood flow to multiple organ systems. The resultant ischemic damage to end organs, including the skin, kidneys, brain, lungs, liver, eyes, and GI tract, can result in multisystem failure. Despite the severity of hemorrhagic complications, microvascular thrombosis represents a significant cause of morbidity and mortality in patients with acute DIC.

Table 17-10

Clinical Conditions Associated with Disseminated Intravascular Coagulation

Sepsis/Severe Infection (Any Microorganism)
Malignancy
Myeloproliferative/lymphoproliferative diseases Solid tumors
Obstetric States
Abruptio placentae Amniotic fluid embolism
Eclampsia
Retained dead fetus
Septic or saline abortion
Tissue Injury
Burns Crush injuries
Extensive surgery
Fat embolism
Multiple trauma
Vascular Disorders
Giant hemangioma Large vascular aneurysms
Kasabach–Merritt syndrome
Severe Toxic or Immunologic Reactions

Intravascular hemolysis (e.g., hemolytic transfusion reactions)
Recreational drugs
Severe allergic or anaphylactic reaction
Snake bites
Transplant rejection
Miscellaneous
Acidosis
Acute respiratory distress syndrome
Cardiopulmonary bypass
Heat stroke
Hypovolemia
Severe hepatic failure
Severe pancreatitis

Treatment

CASE 17-4, QUESTION 11: In the course of several hours, E.B. has exhibited more severe GI bleeding. Her Hct has fallen from 43% to 35%. What treatment course should be pursued? Should heparin therapy be given?

The most important element of treatment in patients with DIC is alleviation of the underlying cause to eliminate the stimulus for continued thrombosis and hemorrhage.[106] For E.B., this involves appropriate source control, antibiotic therapy, and supportive measures to correct or prevent the hemodynamic, respiratory, and metabolic manifestations of shock. Fluid replacement, maintenance of BP and CO, and adequate oxygenation are essential components of the treatment of patients with DIC.

Table 17-11

International Society on Thrombosis and Haemostasis Disseminated Intravascular Coagulation Scoring System

Does the patient have an underlying disorder known to be associated with DIC? (If YES, continue with scoring.)		
Laboratory Test	**Result**	**Point Score**
Platelet count	>100,000	0
	<100,000	1
	<50,000	2

Fibrin-related markers	No increase	0
	Moderate increase[a]	2
	Strong increase[a]	3
Prolonged PT (vs. baseline)	<3 seconds	0
	3–6 seconds	1
	>6 seconds	2
Fibrinogen	>1 g/L	0
	<1 g/L	1
TOTAL SCORE	≥5	Compatible with overt DIC (repeat daily)
	<5	Suggestive but not affirmative for non-overt DIC (repeat in 1–2 days)

[a] Most studies used D-dimer assays. Moderate increases were defined as a value above the upper limit of normal (0.4 mcg/L). Strong increases were defined as a value >10 times the upper limit of normal (4 mcg/L).

DIC, disseminated intravascular coagulation; PT, prothrombin time.

Source: Taylor FB Jr et al. Towards definition, clinical and laboratory criteria, and a scoring system for disseminated intravascular coagulation. Thromb Haemost. 2001;86:1327.

The selection of other therapies aimed at correcting the hemorrhagic or thrombotic manifestations of DIC are controversial and to some extent depend on whether hemorrhagic manifestations or thrombotic complications predominate in the clinical presentation. Initial treatment in patients with hemorrhage involves replacement of clotting components that have been consumed in DIC, guided by coagulation laboratory data.[106] Transfusion of platelets, fresh-frozen plasma (containing all clotting factors), cryoprecipitate (containing factor VIII and fibrinogen), or prothrombin complex concentrate (containing factors II, IX, X, and factor VII for 4-factor products) may be necessary, with close monitoring of platelet count and fibrinogen level.

Several approaches to restoring the inherent anticoagulant pathways that are disrupted in DIC have been attempted. Transfusion of antithrombin concentrates may improve survival in DIC associated with sepsis.[106,110] Recombinant human thrombomodulin is a promising new adjuvant therapy that targets the protein C pathway in the pathogenesis of DIC. Recombinant thrombomodulin was associated with a higher degree of resolution of DIC compared with heparin in a randomized clinical trial, but it is not yet commercially available and additional clinical trials are being conducted to confirm its potential role.[111]

Anticoagulation with heparin in patients with DIC is controversial. In theory, because the initial pathologic event in DIC is activation of the clotting system with formation of intravascular thrombin, the antithrombin activity of heparin should prevent further fibrin deposition and subsequent activation of fibrinolysis. However, randomized trials have not been conducted to confirm this potential benefit, and the role of heparin remains controversial. The Scientific and Standardization Committee on DIC of the International Society on Thrombosis and Haemostasis recommends considering therapeutic doses of low molecular weight heparin in DIC cases with predominant thrombosis.[106] The committee also recommends venous thromboembolism prophylaxis with low molecular weight or unfractionated heparin in critically ill, non-bleeding patients with DIC.

Finally, the use of the antifibrinolytic agents such as tranexamic acid and aminocaproic acid to control bleeding is relatively contraindicated. These agents may worsen the thrombotic complications of DIC, particularly if heparin is not used concurrently. However, antifibrinolytic therapy or recombinant activated factor VII (NovoSeven) may be used in patients with life-threatening bleeding, who fail to respond to replacement of clotting components or to heparinization.

Asthma

Timothy H. Self, Cary R. Chrisman, and Christopher K. Finch

CORE PRINCIPLES	CHAPTER CASES
① Asthma is a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role. Airway inflammation also causes an increase in the existing bronchial hyperresponsiveness to a variety of stimuli. Bronchospasm is another key feature of asthma.	**Case 18-1 (Questions 1, 2), Case 18-5 (Question 6), Case 18-14 (Question 1)**
② The clinical presentation of asthma includes recurrent episodes of wheezing, breathlessness, chest tightness, and cough, particularly at night and in the early morning. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment.	**Case 18-1 (Questions 1, 2), Case 18-2 (Questions 1, 7, 8), Case 18-3 (Question 1), Case 18-4 (Question 1), Case 18-7 (Question 1), Case 18-13 (Questions 1–3)**
③ Long-term management of persistent asthma according to national and international guidelines is aimed at reducing airway inflammation. Environmental control, inhaled corticosteroids, and management of comorbidities that worsen asthma are core management principles. Major treatments of acute exacerbations include frequent inhaled short-acting β_2-agonists and systemic corticosteroids.	**Case 18-1 (Questions 4–9), Case 18-2 (Questions 2–6, 9, 10, 12), Case 18-3 (Questions 2–4), Case 18-4 (Question 1), Case 18-5 (Questions 1–5), Case 18-6 (Question 1), Case 18-7 (Questions 1, 2), Case 18-8 (Question 1), Case 18-9 (Question 1), Case 18-10 (Questions 1, 2), Case 18-11 (Question 1), Case 18-13 (Question 3), Case 18-14 (Question 1)**
④ Monitoring parameters include spirometric measures such as forced expiratory volume in 1 second (FEV_1). Patient self-monitoring includes peak expiratory flow (PEF) as well as symptom assessment. Acute-care monitoring includes FEV_1, PEF, arterial O_2 saturation, and arterial blood gases.	**Case 18-1 (Questions 1–3), Case 18-2 (Questions 1, 4, 7, 8, 11)**
⑤ Based on current evidence, the number of therapeutic controversies is relatively small. Which patients should receive long-acting inhaled β_2-agonists is one topic of some debate.	**Case 18-5 (Questions 3, 4), Case 18-16 (Questions 1–4)**

⑥	Patient education is essential for optimal asthma management. Teaching patients with persistent asthma about daily use of preventive therapy is critical. Education regarding correct use of inhalation devices is frequently not done, but is absolutely necessary.	**Case 18-3 (Questions 2, 4), Case 18-5 (Question 2), Case 18-12 (Question 1)**
⑦	Improving outcomes, including reducing emergency department visits, hospitalizations, and unscheduled office visits, and enhancing quality of life are all achievable by use of the principles of national guidelines.	**Case 18-9 (Question 1), Case 18-15 (Question 1)**

ASTHMA

According to the National Institutes of Health (NIH); Expert Panel Report 3 (EPR-3): Guidelines for the Diagnosis and Management of Asthma,[1] asthma is defined as a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role, in particular mast cells, eosinophils, T lymphocytes, neutrophils, and epithelial cells. In susceptible persons, this inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and cough, particularly at night and in the early morning. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment. The inflammation also causes an increase in the existing bronchial hyperresponsiveness to a variety of stimuli.

In 2011, it was estimated that 25.9 million Americans have asthma.[2] It is an underdiagnosed and undertreated condition that is estimated to have overall costs of roughly $56 billion annually in the United States.[2] Asthma was the cause of 2.1 million emergency department visits in 2009, is the leading cause of lost school days in children, and is a common cause of lost workdays among adults.[2]

Mortality from asthma has decreased in the 21st century, from 4,657 deaths in 1999 to 3,447 deaths in 2007 in the United States according to the Centers for Disease Control and Prevention,[3,4] but morbidity and mortality are still unacceptably high, especially in inner-city minority populations. This chapter emphasizes the 2007 NIH EPR-3 guidelines.[1] Application of the principles of these recent guidelines by clinicians and patients is vital to further reducing asthma morbidity and mortality.

Etiology

Childhood-onset asthma is usually associated with atopy, which is the genetic predisposition for the development of immunoglobulin E (IgE)-mediated response to common aeroallergens. Atopy is the strongest predisposing factor in the development of asthma.[1] A very common presentation of asthma is a child with a positive family history of asthma and allergy to tree and grass pollen, house dust mites, household pets, and molds.

Adult-onset asthma may also be associated with atopy, but many adults with asthma have a negative family history and negative skin tests to common aeroallergens. Some of these patients may have nasal polyps, aspirin sensitivity, and sinusitis. In the British 1958 birth cohort study, participants were monitored for wheezing and asthma at periodic intervals from birth into their mid-forties.[5] In the subset of patients who were seemingly asymptomatic during late adolescence and early adulthood, the presence of asthma at 42 years of age was significantly higher in those patients who had a history of wheezing in childhood. Exposure to factors (e.g., wood dust, chemicals) at the workplace that may cause airway inflammation is also important in many adults. Inflammatory mechanisms are similar, but not the same, as in atopic asthma. Some clinicians may still refer to intrinsic asthma when referring to these patients and extrinsic asthma when discussing atopic asthma.

In addition to atopy and exposure to occupational chemical sensitizers being major risk factors for the development of asthma, several contributing factors may increase the susceptibility to the development of the disease in predisposed individuals.[1] These factors include viral infections, small size at birth, diet, exposure to tobacco smoke, and environmental pollutants.[1]

Recent literature has focused on the “hygiene hypothesis,” an imbalance of T_H2 and T_H1 type T lymphocytes, to explain the marked increase in asthma in westernized countries.[1,6] Infants who have older siblings, early exposure to day care, and typical childhood infections are more likely to activate T_H1 responses (protective immunity), resulting in an appropriate balance of T_H1 to T_H2 cells and the cytokines that they produce. On the other hand, if the immune response is predominately from T_H2 cells (which produce cytokines that mediate allergic inflammation), development of diseases such as asthma is more likely. Examples of factors favoring this imbalance include the common use of antimicrobial agents, urban environment, and Western lifestyle. Further insights into the pathogenesis of asthma continue to be discovered.[1,6,7]

Pathophysiology

Asthma is caused by a complex interaction between inflammatory cells and mediators. As noted in the definition of asthma, mast cells, eosinophils, T lymphocytes, neutrophils, and epithelial cells are of central importance. The bronchial epithelium in asthmatic patients has been described as fragile, with various abnormalities including destruction of ciliated cells and overexpression of epidermal growth factors.[1,6] Figure 18-1 depicts the complex interaction of cells and mediators associated with airway inflammation.

After exposure to an asthma-precipitating factor (e.g., aeroallergen), inflammatory mediators are released from bronchial mast cells, macrophages, T lymphocytes, and epithelial cells. These mediators direct the migration and activation of other inflammatory cells, most notably eosinophils, to the airways.[1,6,7] Eosinophils release biochemicals (e.g., major basic protein and eosinophil cationic protein) that cause airway injury, including epithelial damage, mucus hypersecretion, and increased reactivity of smooth muscle.[1,6]

Research continues to determine the role of a subpopulation of T lymphocytes (T_H2) in asthmatic airway inflammation.[1,6] T_H2 lymphocytes release cytokines (e.g., interleukin [IL]-4 and IL-5) that at least partially control the activation and enhanced survival of eosinophils.[1,6] The complexity of airway inflammation is indicated by the fact that at least 27 cytokines may have a role in the pathophysiology of asthma.[6] In addition, at least 18 chemokines (e.g., eotaxins) have been identified that are important in delivery of eosinophils to the airways.[6] Studies have shown the efficacy of experimental humanized monoclonal antibodies against IL4, IL5, and IL13.[8–10] See Case 18-10 later in this chapter regarding anti-IgE therapy. Other potential targets for treatment of severe asthma continue to be discovered.[11,12] One biomarker of airway inflammation is exhaled nitric oxide (NO), which has been used as a treatment guide in chronic asthma.[1] Bronchial NO has been found to be elevated during periods of exacerbations and is measurably decreased with administration of inhaled steroids but not β_2-agonists.[1,13] Failure to adequately minimize severe and long-term airway inflammation in asthma may result in airway remodeling in some patients. Airway remodeling refers to structural changes, including an alteration in the amount and composition of the extracellular matrix in the airway wall, leading to airflow obstruction that eventually may become only partially reversible.[1]

Hyperreactivity (defined as an exaggerated response of bronchial smooth muscles to trigger stimuli) of the airways to physical, chemical, immunologic, and pharmacologic stimuli is pathognomonic of asthma.[1] Examples of these stimuli include inhaled allergens, respiratory viral infection, cold, dry air, smoke, other pollutants, and methacholine. Endogenous stimuli that can worsen asthma include poorly controlled rhinitis, sinusitis, and gastroesophageal reflux disease.[1] In addition, premenstrual asthma has been reported, but the exact hormonal mechanism is not known.[14]

Although patients with allergic rhinitis, chronic bronchitis, and cystic fibrosis also experience bronchial hyperreactivity, these patients do not experience bronchiolar constriction as severely as do patients with asthma. The degree of bronchial hyperreactivity of asthmatic patients correlates with the clinical course of their disease, which is characterized by periods of remissions and exacerbations. During times of remission, a more intense stimulus is required to produce bronchospasm than during times of increased symptoms. Numerous theories have been proposed to explain the bronchial hyperreactivity found in asthma, yet none fully explains the phenomenon. Inflammation appears to be the primary process in the pathogenesis of bronchial hyperreactivity; however, neurogenic imbalances in the airways also may play a significant role.[1] Hyperreactivity can be measured in the physician's office by having the patient inhale small concentrations of nebulized methacholine or histamine or by exercise (e.g., treadmill). The concentration of aerosolized methacholine or histamine that decreases the forced expiratory volume in 1 second (FEV_1) by 20% is referred to as the PD_{20} or the PC_{20} (provocative dose or concentration that decreases the FEV_1 by 20%).[2] An indicator of optimal anti-inflammatory therapy is an increase in the PD_{20} with time because the airways become less inflamed and therefore less hyperreactive.

Figure 18-1 Airway inflammation. Inhaled antigen activates mast cells and T_H2 cells in the airway. They in turn induce the production of mediators of inflammation (such as histamine and leukotrienes) and cytokines including interleukin-4 and interleukin-5. Interleukin-5 travels to the bone marrow and causes terminal differentiation of eosinophils. Circulating eosinophils enter the area of allergic inflammation and begin migrating to the lung by rolling, through interactions with selectins, and eventually adhering to endothelium through the binding of integrins to members of the immunoglobulin superfamily of adhesion proteins: vascular cell adhesion molecule 1 (VCAM-1) and intercellular adhesion molecule 1 (ICAM-1). Because the eosinophils enter the matrix of the airway through the influence of various chemokines and cytokines, their survival is prolonged by interleukin-4 and granulocyte-macrophage colony-stimulating factor (GM-CSF). On activation, the eosinophil releases inflammatory mediators, such as leukotrienes and granule proteins, to injure airway tissues. In addition, eosinophils can generate GM-CSF to prolong and potentiate their survival and contribution to persistent airway inflammation. MCP-1, monocyte

chemotactic protein; MIP-1α, macrophage inflammatory protein; RANTES, chemokine ligand 5. (Adapted from Busse WW, Lemanske RF, Jr. Asthma. N Engl J Med. 2001;344:350, with permission.)

Another concept related to inflammation is “late-phase” versus “early-phase” asthma (Fig. 18-2). The inhalation of specific allergens in atopic asthmatic patients produces immediate bronchoconstriction (measured by a drop in peak expiratory flow [PEF] or FEV_1) that spontaneously improves in an hour or is reversed easily by inhalation of a β_2-agonist. Although this early asthmatic response (EAR) is blocked by the preadministration of β_2-agonists or theophylline, a second response often occurs ~4 to 8 hours later. This late asthmatic response (LAR) often is more severe, more prolonged, and more difficult to reverse with bronchodilators than is the EAR. The LAR is associated with the influx of inflammatory cells and mediators as described previously. Bronchodilators do not block the LAR to allergen challenge; corticosteroids block the LAR but do not affect the EAR.[1]

Pathologic changes found at autopsy performed on asthmatic patients include (a) marked hypertrophy and hyperplasia of the bronchial smooth muscle, (b) mucous gland hypertrophy and excessive mucus secretion, and (c) denuded epithelium and mucosal edema owing to an exudative inflammatory reaction and inflammatory cell infiltration.[1] Hyperinflation of the lungs from air trapping with extensive mucous plugging is found at autopsy in patients who have died of acute asthma attacks, but these changes also are seen at autopsy in asthmatic patients dying of other causes. The bronchial smooth muscle hypertrophy and mucus hypersecretion are secondary to the chronic inflammatory response.[1,15]

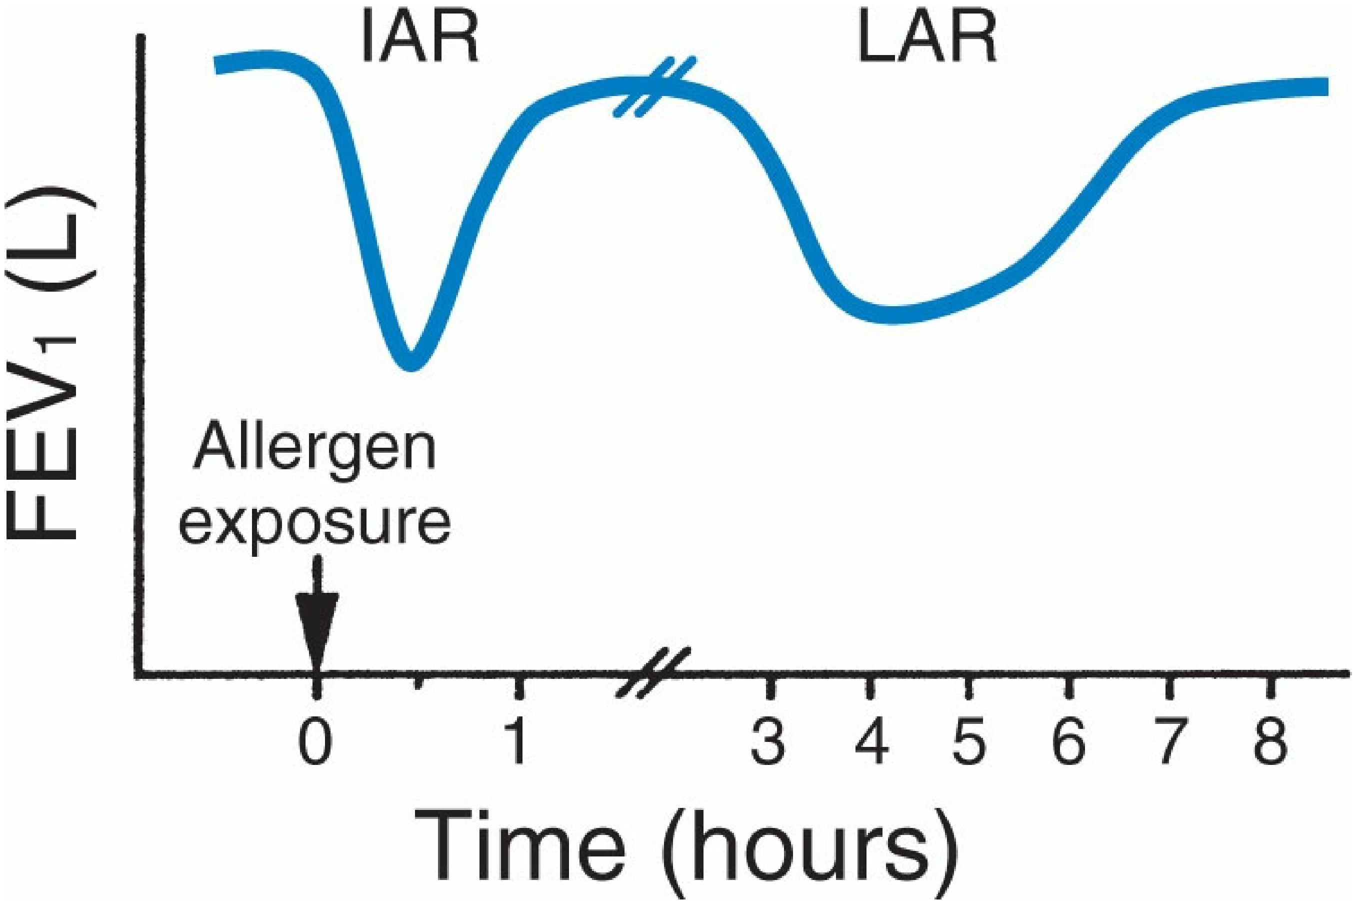

Figure 18-2 Typical immediate and late asthmatic responses seen after exposure to relevant allergen. Immediate asthmatic response (IAR) occurs within minutes, whereas late asthmatic response (LAR) occurs several hours after exposure. Patients may demonstrate isolated IAR, isolated LAR, or dual responses. FEV_1, forced expiratory volume in 1 second. (Adapted from Herfindal ET, Gourley DR, eds. Textbook of Therapeutics Drug and Disease Management. 7th ed. Baltimore, MD: Lippincott Williams & Wilkins; 2003, with permission.)

Symptoms

The heterogeneity of asthma is reflected best in its clinical presentation. Classically, patients with asthma present with intermittent episodes of expiratory wheezing, coughing, and dyspnea. Some patients, however, experience chest tightness or a chronic cough that is not associated with wheezing. There is a wide spectrum of disease severity, ranging from patients with occasional, mild bouts of breathlessness to patients who wheeze daily despite continuous high dosages of medication. In addition, the severity of asthma may be influenced by environmental factors (e.g., specific seasonal allergens). Symptoms often are associated with exercise and sleep (refer to Case 18-11, Case 18-12, and Case 18-14).

Classification of asthma severity is of major importance in defining initial long-term treatment. Within three age groups, EPR-3 uses the classifications of intermittent, mild-persistent, moderate-persistent, and severe-persistent asthma (Tables 18-1–18-3). The frequency of symptoms is a key component of asthma classification.[1] For example, mild-persistent asthma is defined as symptoms more than 2 times per week or nocturnal symptoms (including early morning chest tightness) more than 2 times per month. Many clinicians are unaware that this level of symptoms is defined as persistent asthma. This classification is of major significance when selecting long-term drug therapy in that daily use of anti-inflammatory agents is an essential part of management for persistent asthma.[1]

Diagnosis and Monitoring

HISTORY

The diagnosis of asthma is based primarily on a detailed history of intermittent symptoms of wheezing, chest tightness, shortness of breath, and coughing. These episodes may be worse seasonally (e.g., springtime or late summer and early fall) or in association with exercise. History of nocturnal symptoms with awakening in the early morning is a critical component to assess. In addition, history of symptoms after exposure to other common triggers (e.g., cats, perfume, secondhand tobacco smoke) is typical (Table 18-4). A positive family history and the presence of rhinitis or atopic dermatitis also are significant. After a careful history is obtained, skin testing may be useful in identifying triggering allergens, but it is only of supportive value in the diagnosis of asthma.

Table 18-1

Classifying Asthma Severity in Children 0 to 4 Years of Age

Classifying Severity in Children who are not Currently Taking Long-term Control Medication					
		Classification of Asthma Severity (Children 0–4 Years of Age)			
			Persistent		
Components of Severity		**Intermittent**	**Mild**	**Moderate**	**Severe**
Impairment	Symptoms	≤2 days/week	>2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings	0	1–2×/month	3–4×/month	>1×/week
	SABA use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week but not daily	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Risk	Exacerbations requiring oral	0–1/year	≥2 exacerbation in 6 months requiring oral corticosteroids or ≥4 wheezing episodes in 1 year lasting >1 day AND risk		

	systemic corticosteroids	factors for persistent asthma
		Consider severity and interval since last exacerbation.
		← Frequency and severity may fluctuate with time. →
		Frequency and severity may fluctuate with time.
		Exacerbations of any severity may occur in patients in any severity category.

Level of severity is determined by both impairment and risk. Assess impairment domain by caregiver's recall of previous 2–4 weeks. Assign severity to the most severe category in which any feature occurs.
At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. For treatment purposes, patients who had ≥2 exacerbations requiring oral corticosteroids in the past 6 months, or ≥4 wheezing episodes in the past year, and who have risk factors for persistent asthma may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.

Classifying Severity in Patients After Asthma Becomes Well Controlled, by Lowest Level of Treatment Required to Maintain Control

	Classification of Asthma Severity			
		Persistent		
	Intermittent	**Mild**	**Moderate**	**Severe**
Lowest level of treatment required to maintain control (See Fig. 18-6 for treatment steps.)	Step 1	Step 2	Step 3 or 4	Step 5 or 6

EIB, exercise-induced bronchospasm; SABA, short-acting inhaled β_2-agonist.

Table 18-3

Classifying Asthma Severity in Youths ≥12 Years of Age and Adults

Classifying Severity in Patients who are not Currently Taking Long-term Control Medication

	Classification of Asthma Severity (Youths ≥12 Years of Age and Adults)	

Components of Severity		**Intermittent**	**Persistent** **Mild**	**Moderate**	**Severe**
Impairment	Symptoms	≤2 days/week	>2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings	≤2×/month	3–4×/month	>1×/week but not nightly	Often 7×/week
	SABA use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week but not >1×/day	Daily	Several times per day
Normal FEV_1/FVC:					
8–19 years, 85%20–39 years, 80%40–59 years, 75%60–80 years, 70%	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	■ Normal FEV_1 between exacerbations			
		■ FEV_1 >80% predicted	■ FEV_1 ≥80% predicted	■ FEV_1 >60% but <80% predicted	■ FEV_1 <60% predicted
		■ FEV_1/FVC normal	■ FEV_1/FVC normal	■ FEV_1/FVC reduced 5%	■ FEV_1/FVC reduced >5%
Risk	Exacerbations requiring oral systemic corticosteroids	0–1 in 1 year (see note)	≥2 in 1 year (see note) →		
		Consider severity and interval since last exacerbation. frequency and ← Severity may fluctuate with time for patients in any severity category. → Severity may fluctuate with time for patients in any severity category. Relative annual risk of exacerbations may be related to FEV_1.			

Level of severity is determined by assessment of both impairment and risk. Assess impairment domain by patient's or caregiver's recall of previous 2–4 weeks and spirometry. Assign severity to the most severe category in which any feature occurs.

At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. In general, more frequent and intense exacerbations (e.g., requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate greater underlying disease severity. For treatment purposes, patients who had ≥2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.

Classifying Severity in Patients After Asthma Becomes Well Controlled, by Lowest Level of Treatment Required to Maintain Control

	Classification of Asthma Severity			
		Persistent		
	Intermittent	**Mild**	**Moderate**	**Severe**

Lowest level of treatment required to maintain control (See Fig. 18-8 for treatment steps.)	Step 1	Step 2	Step 3 or 4	Step 5 or 6

EIB, exercise-induced bronchospasm; FEV_1, forced expiratory volume in 1 second: FVC, forced vital capacity; ICU, intensive care unit; SABA, short-acting β_2-agonist.

Table 18-4

Sample Questions for the Diagnosis and Initial Assessment of Asthma

A "yes" answer to any question suggests that an asthma diagnosis is likely.[a]
In the past 12 months
■ Have you had a sudden severe episode or recurrent episodes of coughing, wheezing (high-pitched whistling sounds when breathing out), chest tightness, or shortness of breath? ■ Have you had colds that "go to the chest" or take more than 10 days to get over? ■ Have you had coughing, wheezing, or shortness of breath during a particular season or time of the year? ■ Have you had coughing, wheezing, or shortness of breath in certain places or when exposed to certain things (e.g., animals, tobacco smoke, perfumes)? ■ Have you used any medications that help you breathe better? How often? ■ Are your symptoms relieved when the medications are used?
In the past 4 weeks, have you had coughing, wheezing, or shortness of breath
■ At night that has awakened you? ■ On awakening? ■ After running, moderate exercise, or other physical activity?

[a] These questions are examples and do not represent a standardized assessment or diagnostic instrument. The validity and reliability of these questions have not been assessed.

Reprinted from National Institutes of Health. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. Bethesda, MD: National Heart, Lung, and Blood Institute; 2007. NIH publication 07-4051.

PULMONARY FUNCTION TESTS

The diagnosis of asthma is based in part on demonstration of reversible airway obstruction. A brief discussion of tests to detect reversibility of airway obstruction is important. Furthermore, a short summary of arterial blood gases (ABGs) is pertinent here in assessing the severity of asthma exacerbations.

Spirometry

Lung volumes often are measured to obtain information about the size of the patient's lungs because pulmonary diseases can affect the volume of air that can be inhaled and exhaled. The tidal volume is the volume of air inspired or expired during normal breathing. The volume of air blown off after maximal inspiration to full expiration is defined as the vital capacity (VC). The residual volume (RV) is the volume of air left in the lung after maximal expiration. The volume of air left after a normal expiration is the functional residual capacity (FRC). Total lung capacity (TLC) is the VC plus the RV. Patients with obstructive lung disease have difficulty with expiration; therefore, they tend to have a decreased VC, an increased RV, and a normal TLC. Classic restrictive lung diseases (e.g., sarcoidosis, idiopathic pulmonary fibrosis) present with decrements in all lung volumes.[16] Patients also may have mixed lesion diseases, in which case the classic findings are not apparent until the disease has advanced considerably.

The spirometer also can be used to evaluate the performance of the patient's lungs, thorax, and respiratory muscles in moving air into and out of the lungs. Forced expiratory maneuvers amplify the ventilation abnormalities produced. The single most useful test for ventilatory dysfunction is the forced expiratory volume (FEV). The FEV is measured by having the patient exhale into the spirometer as forcefully and completely as possible after maximal inspiration. The resulting volume curve is plotted against time (Fig. 18-3) so that expiratory flow can be estimated.

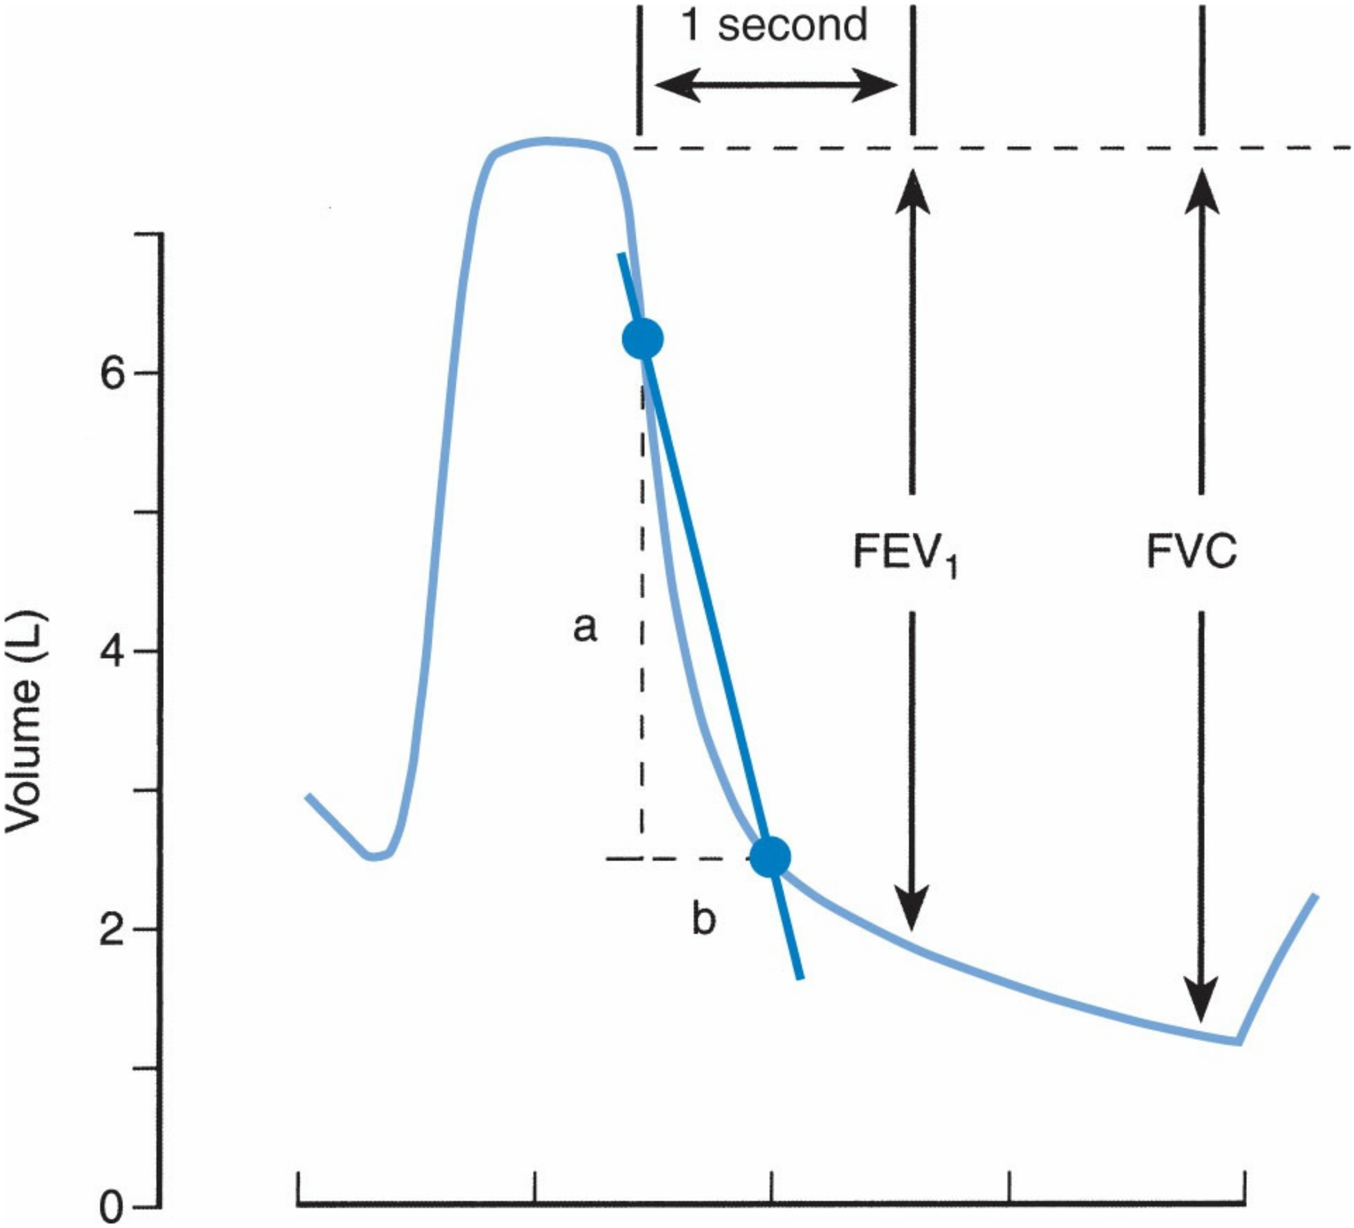

Figure 18-3 Volume–time curve from a forced expiratory maneuver. FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity.

For a video that shows how to take a lung function test, see http://www.european-lung-foundation.org/index.php?id=15411.

Standard spirometers contain pneumotachographs in the mouthpieces that can measure airflow directly. A number of important measures of lung function are made from the resulting flow–volume curves. The advantages of this technique include a display of simultaneous flows at any lung volume, visual estimation of patient effort and cooperation, high reproducibility within as well as across individuals, and an analysis of the distribution of flow limitation.[16,17] The FEV_1 of the forced vital capacity (FVC, the maximal volume of air exhaled with maximally forced effort from a position of maximal inspiration) commonly is measured to determine the dynamic performance of the lung in moving air. The FEV_1 usually is expressed as a percentage of the total volume of air exhaled and is reported as the FEV_1-to-FVC ratio. Healthy persons generally can exhale at least 75% to 80% of their VC in 1 second and almost all of it in 3 seconds. Thus, the FEV_1 normally is 80% of the FVC. The patient's breathing ability is compared against "predicted normal" values for patients with similar physiologic characteristics because lung volumes depend on age, race, sex, height, and weight. For example, an average-sized young adult man may have an FVC of 4 to 5 L and a corresponding FEV_1 of 3.2 to 4 L. The FEV_1 and the FVC are the most reproducible of the pulmonary function tests.

Peak Expiratory Flow

The PEF is the maximal flow that can be produced during the forced expiration. The PEF can be measured easily with various handheld peak flow meters and commonly is used in emergency departments (EDs) and clinics to quickly and objectively assess the effectiveness of bronchodilators in the treatment of acute asthma attacks. Peak flow meters also can be used at home by patients with asthma to assess chronic therapy. The changes in PEF generally parallel those of the FEV_1; however, the PEF is a less reproducible measure than the FEV_1.[1] A healthy, average-sized young adult man typically has a PEF of 550 to 700 L/minute. Commercial peak flow meters come with a chart for patients to determine their predicted normal PEFs based on their sex, age, and height.

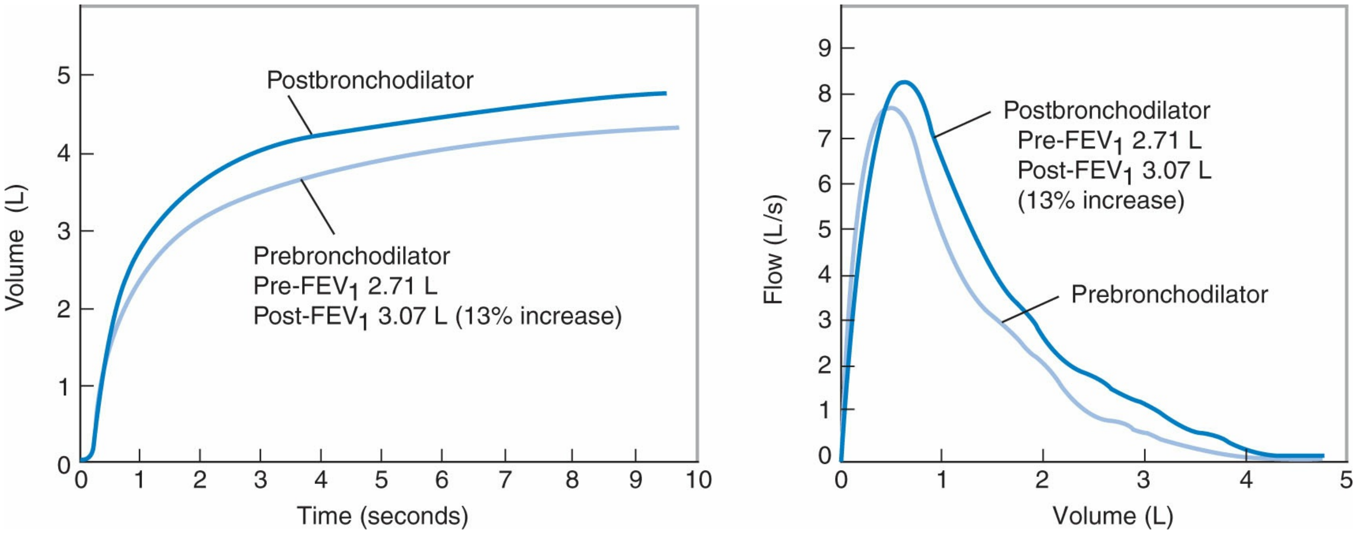

Figure 18-4 Interpretation of results of spirometry. The graphs depicted are for illustration only. The interpretation of flow rates may vary with the age of the patient. FEV_1, forced expiratory volume in 1 second. (Adapted from National Institutes of Health. Expert Panel Report 2. Guidelines for the Diagnosis and Management of Asthma. Bethesda, MD: National Heart, Lung, and Blood Institute; 1997. NIH publication 97-4051.)

OBSTRUCTIVE VERSUS RESTRICTIVE AIRWAY DISEASE

Generally, pulmonary disorders fall into two categories: those that restrict the lungs and thorax and those that obstruct them. In simplest terms, restrictive disease limits airflow during inspiration, and obstructive disease limits airflow during expiration.

Restrictive disease results from a loss of elasticity (e.g., fibrosis, pneumonia) or physical deformities of the chest (e.g., kyphoscoliosis), with a consequent inability to expand the lung and a reduced TLC. Whereas restrictive airway diseases limit lung expansion, obstructive airway diseases (e.g., bronchitis, asthma) narrow air passages, create air turbulence, and increase resistance to airflow. In obstructive diseases, maximal expiration may begin at higher-than-normal lung volumes, and the expiratory flow is depressed.

REVERSIBLE AIRWAY OBSTRUCTION

Spirometry often is used to determine the reversibility of airway disease. Although many generally associate reversibility with bronchospasm, therapy can improve airflow by reversing any of the causative pathologic processes of asthma described previously. Significant clinical reversibility produced from bronchodilators is determined by the tests outlined in Figure 18-4. The FEV_1 is considered the gold standard test for determining reversibility of airway disease and bronchodilator efficacy. Significant clinical reversibility is defined as a 12% improvement in FEV_1 after administration of a short-acting bronchodilator.[1] An improvement of 20% in FEV_1 provides noticeable subjective relief of respiratory symptoms in most patients. For patients with a very low baseline FEV_1 (e.g., <1 L), an absolute improvement of 250 mL sometimes is considered a better indicator of therapeutic benefit than assessing percentage of change. In either case, the patient's subjective clinical impression also should be considered when using pulmonary function testing and drug challenges as predictors for future therapy.

BLOOD GAS MEASUREMENTS

The best indicators of overall lung function (ventilation and diffusion) are the ABGs (i.e., arterial partial pressure of oxygen [Pao_2], arterial partial pressure of carbon dioxide [$Paco_2$], and pH). Although ABG measurements also are dependent on the patient's cardiovascular status, they are indispensable in assessing both acute and chronic changes in pulmonary patients. (See Chapter 26, Acid–Base Disorders, for a review of ABGs.) Another means of assessing the patient's ability to oxygenate tissues adequately is to measure oxygen saturation, which is described by the following equation:

$$O_2 \text{ saturation} = \text{Quantity of } O_2 \text{ actually bound to hemoglobin} / \text{Quantity of } O_2 \text{ that can be bound to hemoglobin} \times 100 \qquad \text{(Eq. 18-1)}$$

According to this equation, oxygen saturation is the ratio between the actual amount of oxygen bound to hemoglobin and the potential amount of oxygen that could be bound to hemoglobin at a given pressure. The denominator in the preceding equation is the oxygen capacity. The normal oxygen saturation of arterial blood at a Pao_2 of 100 mm Hg is 97.5% and that of mixed venous blood at a Po_2 of 40 mm Hg is about 75%.[16]

Oxygen saturations can be measured continuously with transcutaneous monitors. This type of monitoring (pulse oximetry) is extremely helpful in determining whether supplemental oxygen therapy is indicated in patients with various chronic respiratory diseases. At a Pao_2 of less than 60 mm Hg, oxygen saturation begins to drop precipitously (Fig. 18-5).

Goals of Therapy

The EPR-3[1] established the following goals of therapy to achieve control of asthma:

Reduce Impairment: (a) Prevent chronic and troublesome symptoms (e.g., coughing or breathlessness in the night, in the early morning, or after exertion); (b) maintain (near) "normal" pulmonary function; (c) maintain normal activity levels (including exercise, other physical activities, and attendance at work or school); (d) require infrequent use of short-acting inhaled β_2-agonists ([SABAs], ≤2 days a week for quick relief of symptoms); and (e) meet patients' and families' expectations of and satisfaction with asthma care.

Reduce Risk: (a) Prevent recurrent exacerbations of asthma and minimize the need for ED visits or hospitalizations; (b) prevent progressive loss of lung function—for children, prevent reduced lung growth; and (c) provide optimal pharmacotherapy with minimal or no adverse effects.

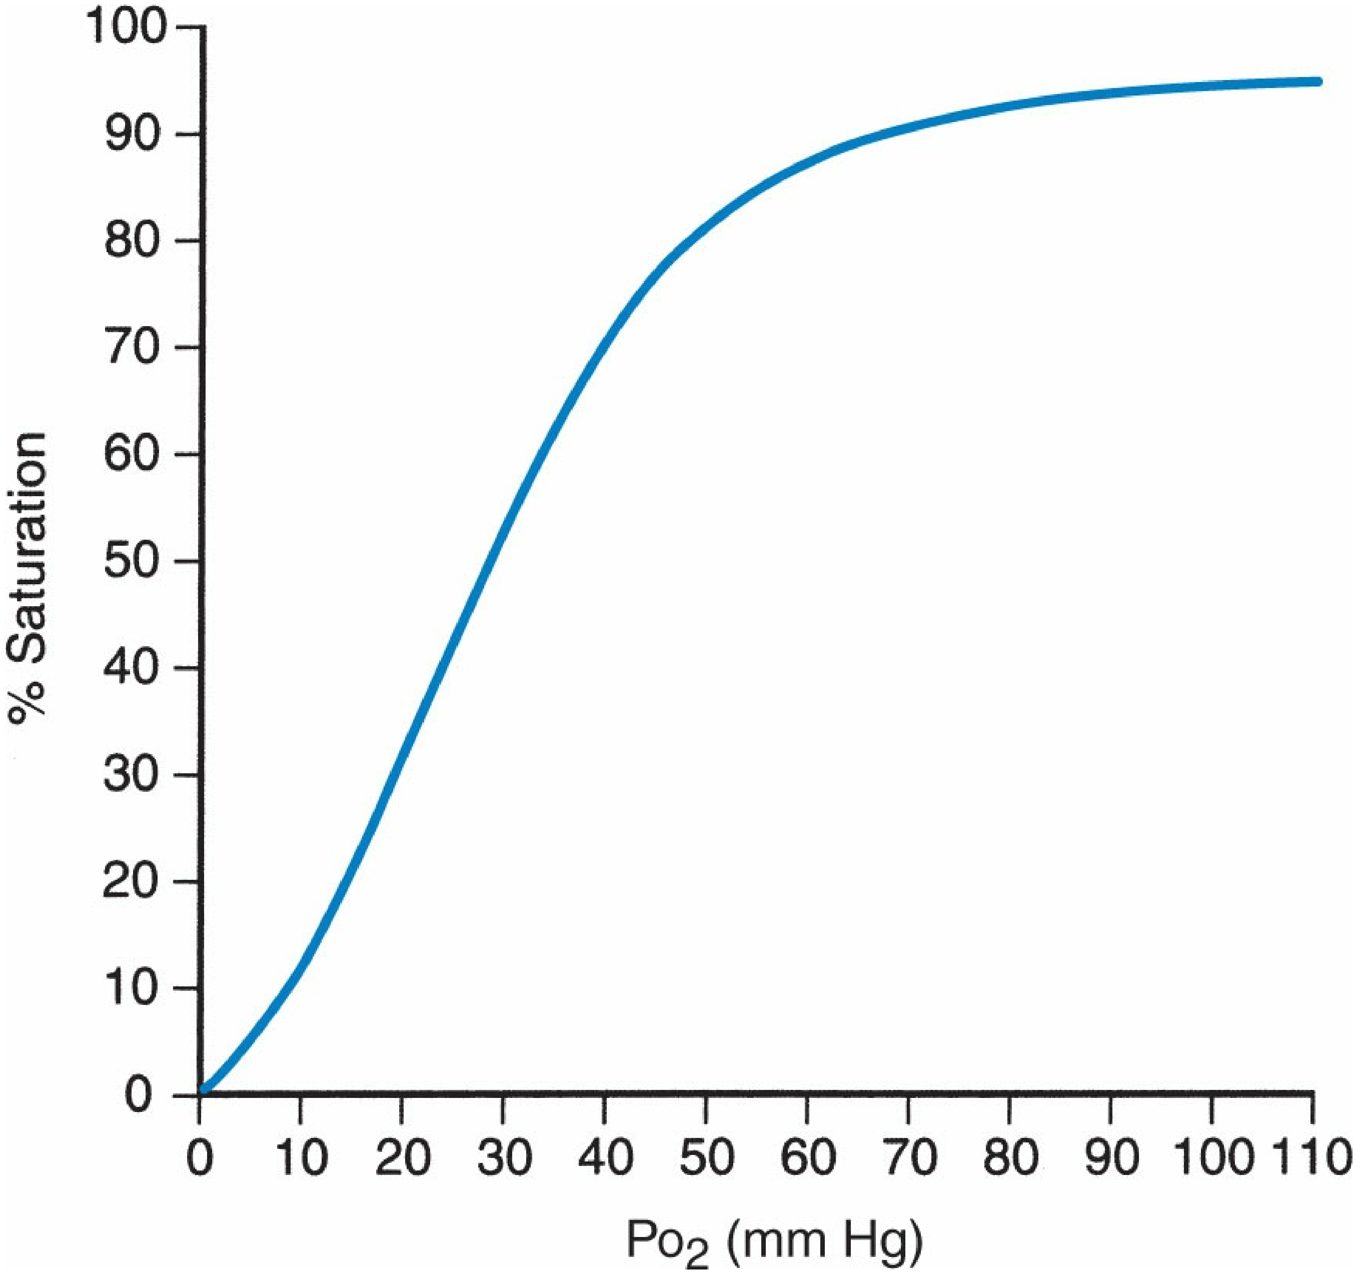

Figure 18-5 The oxygen dissociation curve reveals that the percent saturation of hemoglobin increases almost linearly with increases in the arterial O_2 tension until a partial pressure of arterial oxygen (Pao_2) of 55 to 65 mm Hg is reached. At Pao_2 values above this, the increase in hemoglobin saturation becomes proportionately less, and relatively little additional oxygen is added to the hemoglobin despite large increases in Pao_2. (Adapted from Guenther CA, Welch MH. Pulmonary Medicine. 2nd ed. Philadelphia, PA: JB Lippincott; 1982, with permission.)

MAJOR COMPONENTS OF LONG-TERM MANAGEMENT

To achieve these goals of therapy, EPR-3[1] also outlines some general treatment principles. Asthma management has four major components, including (a) measures of asthma assessment and monitoring, (b) education for a partnership in asthma care, (c) control of environmental factors and comorbid conditions that affect asthma, and (d) medications. Optimal long-term management requires a continuous-care approach, including each of these four major components, to prevent exacerbations and decrease airway inflammation. Early therapeutic interventions in managing acute exacerbations are very important in decreasing the chance of severe narrowing of the airways. Achieving the goals of asthma therapy also involves individualizing each patient's therapy. In addition, optimal care involves establishing a "partnership" between the patient, the patient's family, and the clinician.

For most patients with asthma, the condition can be well controlled by using the step-care approach recommended by EPR-3[1] (Figs. 18-6–18-8). A concerted effort in patient education as an integral part of state-of-the-art long-term management has been demonstrated to improve outcomes, including quality of life in patients with asthma. Because of the excellent outcomes associated with optimal long-term management, if a patient requires an ED visit or hospitalization, great care should be given to determining how the acute-care visit could have been prevented.

ACUTE ASTHMA

Assessment

SIGNS AND SYMPTOMS

CASE 18-1

QUESTION 1: Q.C., a 6-year-old, 20-kg girl, presents to the ED with complaints of dyspnea and coughing that have progressively worsened during the past 2 days. These symptoms were preceded by 3 days of symptoms of a viral upper respiratory tract infection (sore throat, rhinorrhea, and coughing). She has experienced several bouts of bronchitis in the last 2 years and was hospitalized for pneumonia 3 months ago. Q.C. is not being treated with any medications at present. Physical examination reveals an anxious-appearing young girl in moderate respiratory distress with audible expiratory wheezes; occasional coughing; a prolonged expiratory phase; a hyperinflated chest; and suprasternal, supraclavicular, and intercostal retractions. Bilateral inspiratory and expiratory wheezes with decreased breath sounds on the left side are heard on auscultation. Q.C.'s vital signs are as follows: respiratory rate (RR), 30 breaths/minute; blood pressure (BP), 110/83 mm Hg; heart rate, 130 beats/minute; temperature, 37.8°C; and pulsus paradoxus, 18 mm Hg. Her arterial oxygen saturation (Sao_2) by pulse oximetry is 90%. Q.C. is given O_2 to maintain Sao_2 greater than 90% and 2.5 mg of albuterol by nebulizer every 20 minutes for three doses. After the initial treatment, Q.C. claims some subjective improvement and appears to be more comfortable; however, wheezing on auscultation becomes louder. What signs and symptoms in Q.C. are consistent with acute bronchial obstruction? Does increased wheezing after albuterol indicate failure of the medication?

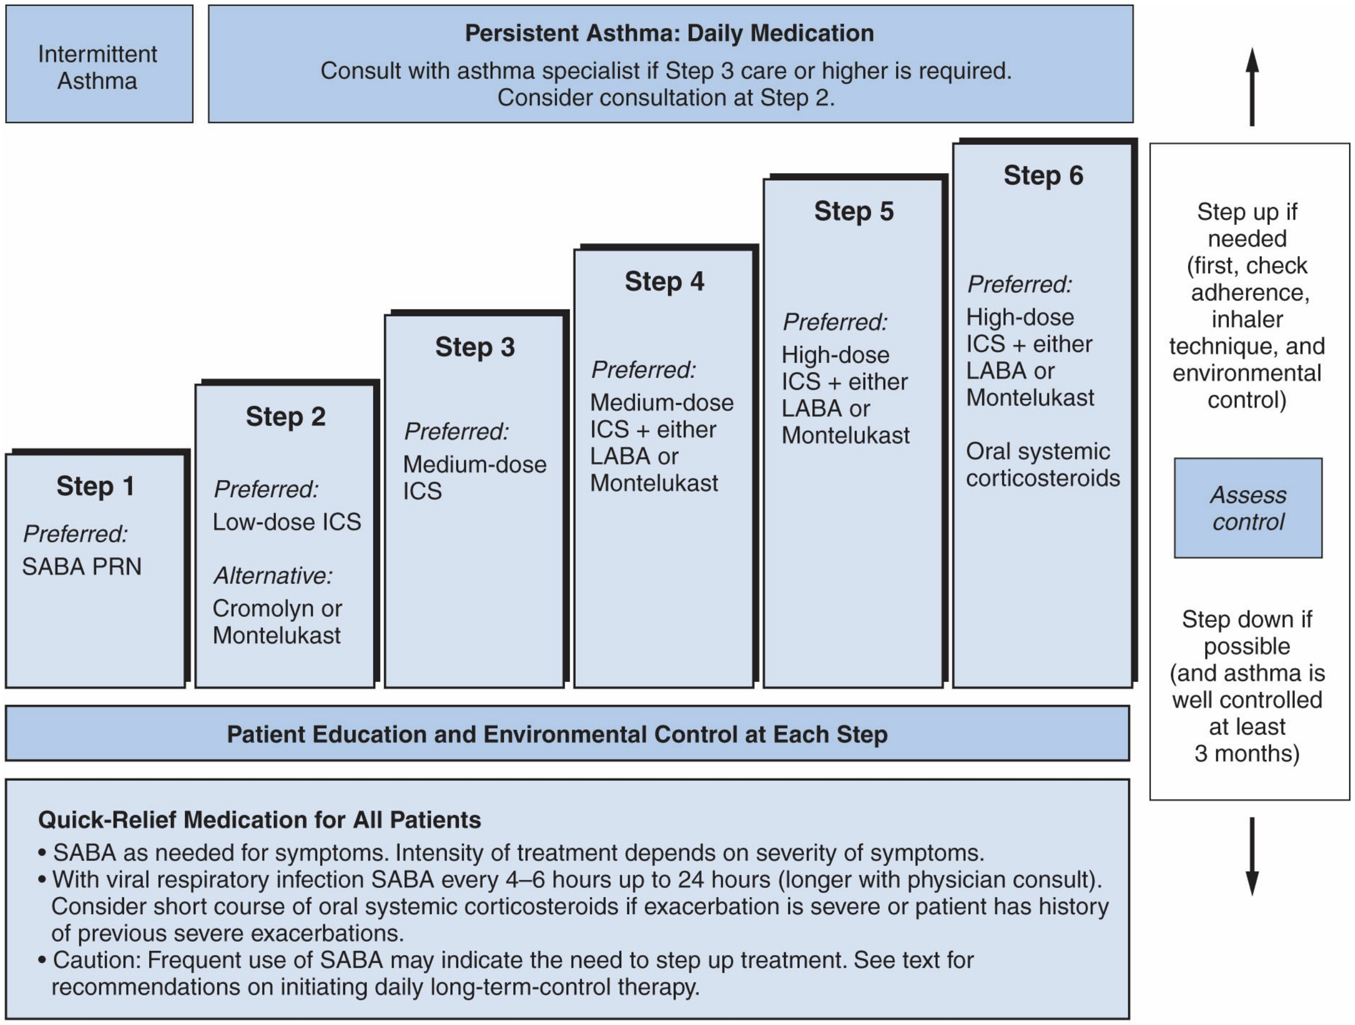
Asthma is an obstructive lung disease; therefore, the primary limitation to airflow occurs during expiration. This outflow obstruction leads to the classic findings of dyspnea, expiratory wheezes, and a prolonged expiratory phase during the ventilatory cycle.[1] Wheezing is a whistling sound produced by turbulent airflow through a constricted opening and usually is more prominent on expiration. Thus, the audible expiratory wheezing in Q.C. is compatible with bronchial obstruction. In fact, Q.C.'s obstruction is so severe that even inspiratory wheezes and decreased air movement were detected on auscultation. It is important to realize that the classic symptom of wheezing requires turbulent airflow; therefore, effective therapy of acute asthma actually may result in increased wheezing initially because airflow increases throughout the lung. As a result, Q.C.'s increased wheezing on auscultation is compatible with her clinical improvement after the albuterol nebulizer treatments.

The coughing experienced by Q.C. is another common finding associated with acute asthma attacks. The coughing may be caused by stimulation of “irritant receptors” in the bronchi by the chemical mediators of inflammation (e.g., leukotrienes) that are released from mast cells or from the mechanics of smooth muscle contraction.

In the progression of an asthma attack, the small airways become completely occluded during expiration, and air can be trapped behind the occlusion; therefore, the patient has to breathe at higher-than-normal lung volumes.[1] Consequently, the thoracic cavity becomes hyperexpanded, and the diaphragm is lowered. As a result, the patient must use the accessory muscles of respiration to expand the chest wall. Q.C.’s hyperinflated chest and her use of suprasternal, supraclavicular, and intercostal muscles to assist in breathing also are compatible with obstructive airway diseases.

Occlusion of the small airways, air trapping, and resorption of air distal to the obstruction can lead to atelectasis (incomplete expansion or collapse of pulmonary alveoli or of a segment of a lobe of the lung). Localized areas of atelectasis often are difficult to distinguish from infiltrates on a chest radiograph, and atelectasis can be mistaken for pneumonia.

Q.C.’s history of multiple bouts of “bronchitis” is significant and typical of many young asthmatic patients. In any patient with recurring episodes of bronchial symptoms (i.e., bronchitis, pneumonia), the possible diagnosis of asthma should be investigated.



Intermittent Asthma

Persistent Asthma: Daily Medication

Consult with asthma specialist if Step 3 care or higher is required.
Consider consultation at Step 2.

Step 1
Preferred:
SABA PRN

Step 2
Preferred:
Low-dose ICS
Alternative:
Cromolyn or Montelukast

Step 3
Preferred:
Medium-dose ICS

Step 4
Preferred:
Medium-dose ICS + either LABA or Montelukast

Step 5
Preferred:
High-dose ICS + either LABA or Montelukast

Step 6
Preferred:
High-dose ICS + either LABA or Montelukast
Oral systemic corticosteroids

Step up if needed (first, check adherence, inhaler technique, and environmental control)

Assess control

Step down if possible (and asthma is well controlled at least 3 months)

Patient Education and Environmental Control at Each Step

Quick-Relief Medication for All Patients

- SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms.
- With viral respiratory infection SABA every 4–6 hours up to 24 hours (longer with physician consult). Consider short course of oral systemic corticosteroids if exacerbation is severe or patient has history of previous severe exacerbations.
- Caution: Frequent use of SABA may indicate the need to step up treatment. See text for recommendations on initiating daily long-term-control therapy.

Key: **Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy.** ICS, inhaled corticosteroid; LABA, inhaled long-acting β_2-agonist; SABA, inhaled short-acting β_2-agonist.

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision-making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- If clear benefit is not observed within 4–6 weeks and patient/family medication technique and adherence are satisfactory, consider adjusting therapy or alternative diagnosis.
- Studies on children 0–4 years of age are limited. Step 2 preferred therapy is based on Evidence A. All other recommendations are based on expert opinion and extrapolation from studies in older children.

Figure 18-6 Stepwise approach for managing asthma in children 0 to 4 years of age. (Reprinted from National Institutes of Health. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. Bethesda, MD: National Heart, Lung, and Blood Institute; 2007. NIH publication 07-4051.)

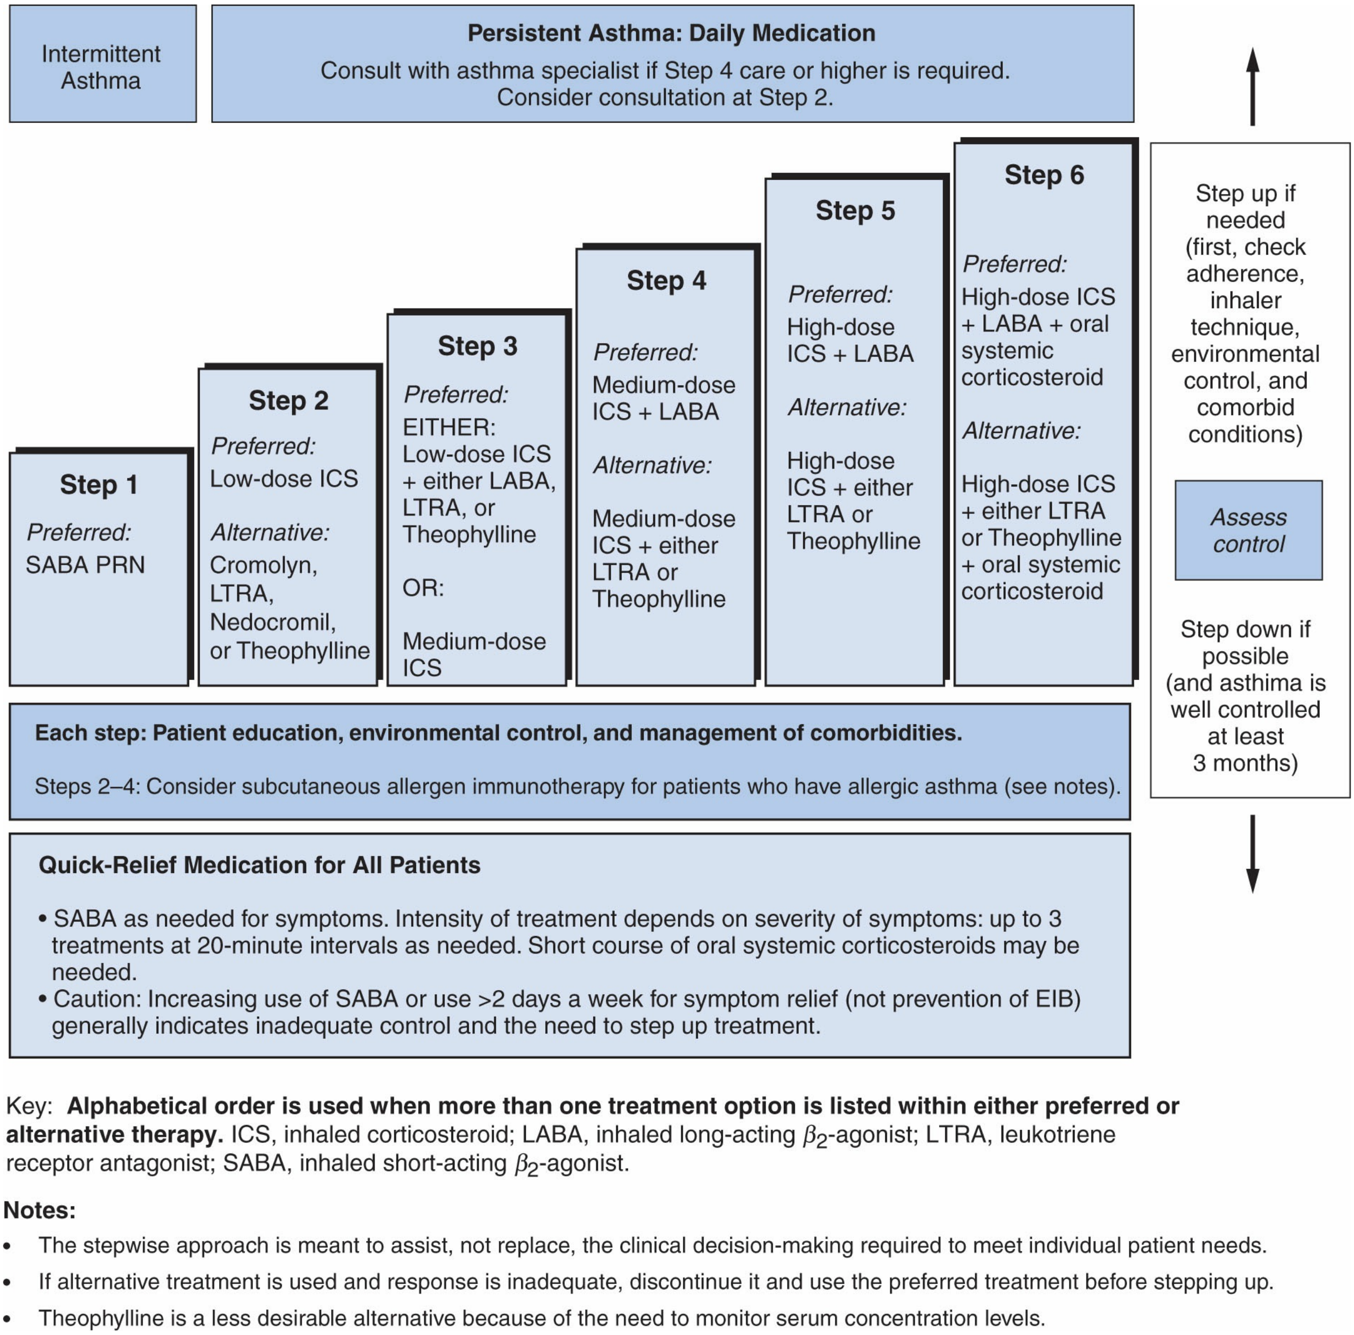
The increased pulse, RR, and anxiety experienced by Q.C. can be attributed to both the hypoxemia and the feeling of suffocation. The hypoxemia in acute asthma is caused principally by an imbalance between alveolar ventilation and pulmonary capillary blood flow, also known as ventilation–perfusion mismatching.[16] Each alveolus of the lung is supplied with capillaries from the pulmonary artery for gas exchange. When ventilation is decreased to an area of the lung, the alveoli in that area become hypoxic, and the pulmonary artery to that region constricts as a normal physiologic response. As a result, blood flow is shunted to the well-ventilated portions of the lung because of the need to preserve adequate oxygenation of the blood. The pulmonary arteries, however, are not constricted completely, and when a small amount of blood flows to the poorly ventilated alveoli, mismatching is the result. Conditions of diffuse bronchial obstruction (i.e., acute asthma) increase the amount of mismatching. In addition, some mediators of acute bronchospasm (e.g., histamine) further worsen mismatching by constricting bronchial smooth muscle while concurrently relaxing vascular smooth muscle.

Q.C. also demonstrated a significant pulsus paradoxus. Pulsus paradoxus is defined as a drop in systolic BP of more than 10 mm Hg with inspiration. In general, pulsus paradoxus correlates with the severity of bronchial obstruction; however, it is not always present.[1]

EXTENT OF OBSTRUCTION

CASE 18-1, QUESTION 2: What additional tests would be helpful in assessing the extent of pulmonary obstruction in Q.C.?

Chest radiographs are not recommended routinely but should be obtained in patients who are suspected of having a complication (e.g., pneumonia).[1] Hyperinflated lungs and areas of atelectasis can be seen on a chest X-ray film; however, chest X-ray studies usually are negative and of little value in evaluating acute asthma attacks. The finding of a local decrease in breath sounds in Q.C.'s left lung may justify the need for a chest X-ray study, particularly if a significant differential in air movement persists after initial therapy. A local decrease in breath sounds may indicate pneumonia, aspiration of a foreign object, pneumothorax, or merely thickened mucous plugging of a large bronchus.



Intermittent Asthma
Persistent Asthma: Daily Medication
Consult with asthma specialist if Step 4 care or higher is required.
Consider consultation at Step 2.
Step 1
Preferred:
SABA PRN
Step 2
Preferred:
Low-dose ICS
Alternative:
Cromolyn, LTRA, Nedocromil, or Theophylline
Step 3
Preferred:
EITHER:
Low-dose ICS + either LABA, LTRA, or Theophylline
OR:
Medium-dose ICS
Step 4
Preferred:
Medium-dose ICS + LABA
Alternative:
Medium-dose ICS + either LTRA or Theophylline
Step 5
Preferred:
High-dose ICS + LABA
Alternative:
High-dose ICS + either LTRA or Theophylline
Step 6
Preferred:
High-dose ICS + LABA + oral systemic corticosteroid
Alternative:
High-dose ICS + either LTRA or Theophylline + oral systemic corticosteroid
Step up if needed (first, check adherence, inhaler technique, environmental control, and comorbid conditions)
Assess control
Step down if possible (and asthma is well controlled at least 3 months)
Each step: Patient education, environmental control, and management of comorbidities.
Steps 2–4: Consider subcutaneous allergen immunotherapy for patients who have allergic asthma (see notes).
Quick-Relief Medication for All Patients

- SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms: up to 3 treatments at 20-minute intervals as needed. Short course of oral systemic corticosteroids may be needed.
- Caution: Increasing use of SABA or use >2 days a week for symptom relief (not prevention of EIB) generally indicates inadequate control and the need to step up treatment.

Key: **Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy.** ICS, inhaled corticosteroid; LABA, inhaled long-acting β_2-agonist; LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting β_2-agonist.

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision-making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- Theophylline is a less desirable alternative because of the need to monitor serum concentration levels.

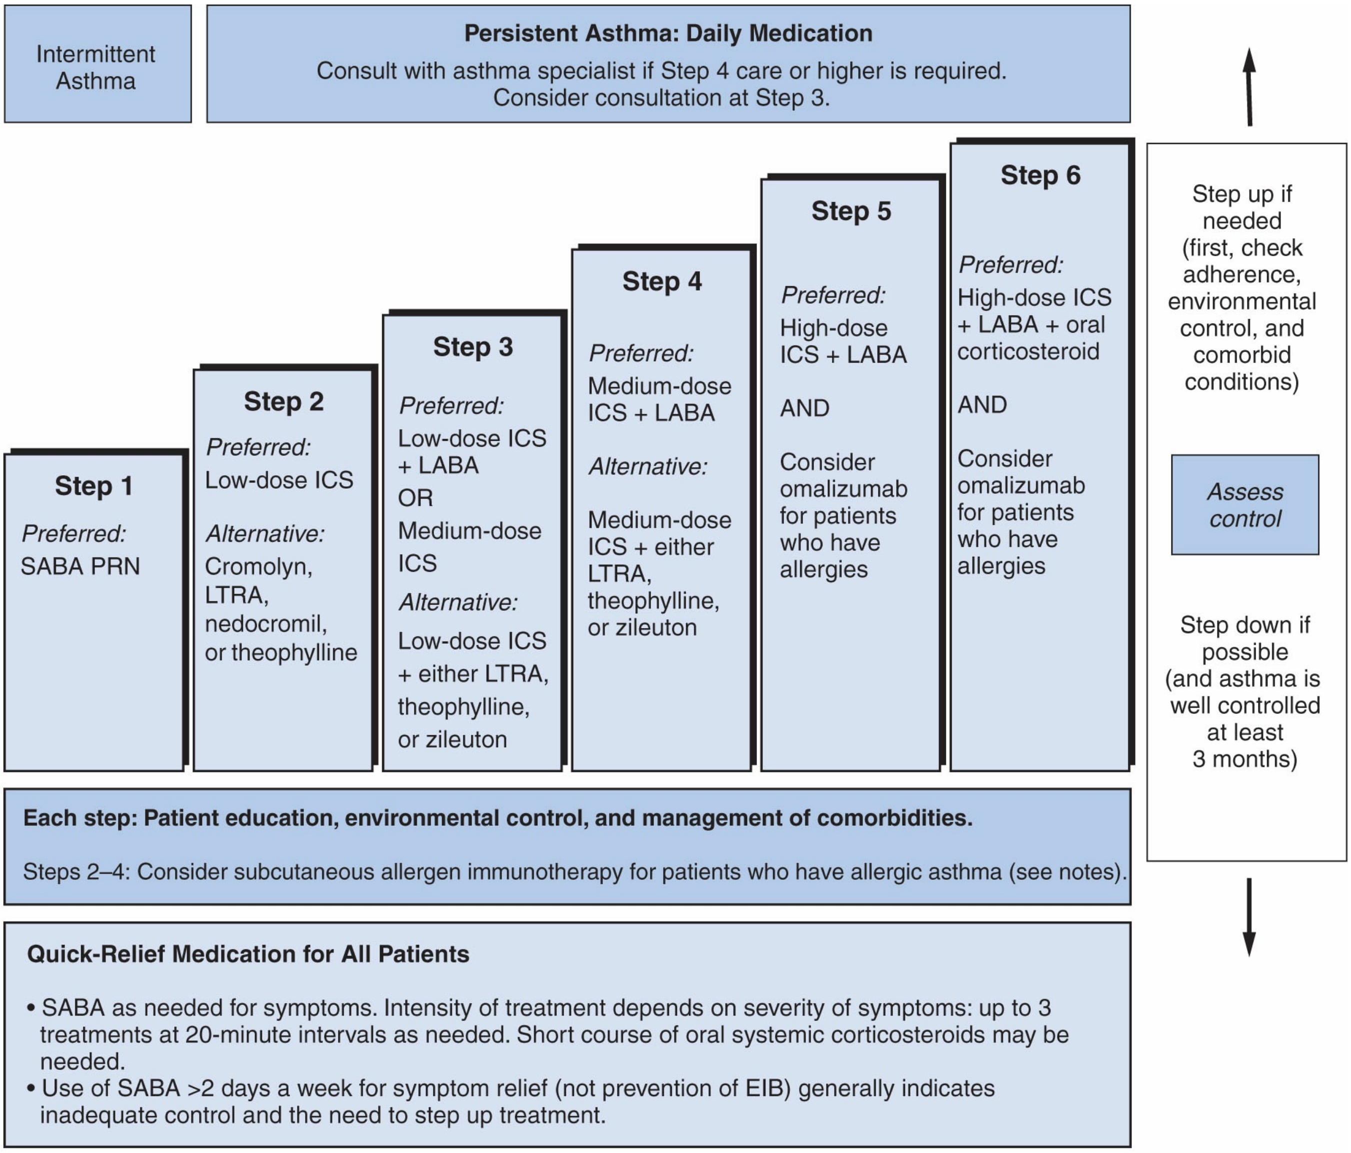
Figure 18-7 Stepwise approach for managing asthma in children 5 to 11 years of age. (Reprinted from National Institutes of Health. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. Bethesda, MD: National Heart, Lung, and Blood Institute; 2007. NIH publication 07-4051.)

Pulmonary function testing (e.g., FEV_1, PEF) provides objective measurement of the degree of airway obstruction. Peak flow meters are helpful in the ED for assessing both the severity of airway obstruction and the response to bronchodilator therapy. Unfortunately, infants and many young children do not have the cognitive or motor skills necessary to perform pulmonary function tests. EPR-3 points out that in one study only 65% of children 5 to 16 years of age could complete either FEV_1 or PEF during an acute exacerbation. Because of Q.C.'s initial anxiety, the PEF should be measured after bronchodilator therapy has been initiated when she may be calmer. One disadvantage of pulmonary function tests in acute asthma is that the forced expiratory maneuver commonly triggers coughing. ABG measurements are the gold standard for assessing very severe airway obstruction.[1] EPR-3[1] suggests ABGs for evaluation of $Paco_2$ in patients who have suspected hypoventilation, severe distress, or FEV_1 or PEF less than 25% of predicted after initial treatment. ABG measurements are indicated in patients who fail to respond adequately to initial therapy or in patients requiring hospitalization; they are not indicated at this time for Q.C. A repeat pulse oximetry at 1 hour after treatment initiation is warranted in Q.C. to ensure adequate arterial oxygen saturation.

NEED FOR HOSPITALIZATION

CASE 18-1, QUESTION 3: Q.C. may require hospitalization. Which clinical test is predictive of the need for admission or whether Q.C. will relapse if sent home from the ED? Are Q.C.'s signs and symptoms predictive of whether she will relapse and return to the ED if not hospitalized?

The most useful predictive tool is the FEV_1 or PEF response to initial treatment. Patients who do not improve to at least 40% of predicted FEV_1 or PEF after initial intensive therapy are more likely to require hospitalization.[1] Although Q.C. is not able to perform spirometry, she is able to execute the PEF maneuver, and the plan is to check her PEF after 1 hour of therapy. Signs and symptom scores alone are not adequate to predict outcome of ED treatment of asthma, but scores along with pulse oximetry and PEF or FEV_1 are helpful predictors.[1]



Intermittent Asthma
Persistent Asthma: Daily Medication
Consult with asthma specialist if Step 4 care or higher is required.
Consider consultation at Step 3.
Step 1
Preferred:
SABA PRN
Step 2
Preferred:
Low-dose ICS
Alternative:
Cromolyn, LTRA, nedocromil, or theophylline
Step 3
Preferred:
Low-dose ICS + LABA
OR
Medium-dose ICS
Alternative:
Low-dose ICS + either LTRA, theophylline, or zileuton
Step 4
Preferred:
Medium-dose ICS + LABA
Alternative:
Medium-dose ICS + either LTRA, theophylline, or zileuton
Step 5
Preferred:
High-dose ICS + LABA
AND
Consider omalizumab for patients who have allergies
Step 6
Preferred:
High-dose ICS + LABA + oral corticosteroid
AND
Consider omalizumab for patients who have allergies
Step up if needed (first, check adherence, environmental control, and comorbid conditions)
Assess control
Step down if possible (and asthma is well controlled at least 3 months)

Each step: Patient education, environmental control, and management of comorbidities.

Steps 2–4: Consider subcutaneous allergen immunotherapy for patients who have allergic asthma (see notes).

Quick-Relief Medication for All Patients

- SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms: up to 3 treatments at 20-minute intervals as needed. Short course of oral systemic corticosteroids may be needed.
- Use of SABA >2 days a week for symptom relief (not prevention of EIB) generally indicates inadequate control and the need to step up treatment.

Key: **Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy.** EIB, exercise-induced bronchospasm; ICS, inhaled corticosteroid; LABA, long-acting inhaled β_2-agonist; LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting β_2-agonist.

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision-making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- Zileuton is a less desirable alternative because of limited studies as adjunctive therapy and the need to monitor liver function. Theophylline requires monitoring of serum concentration levels.
- In step 6, before oral systemic corticosteroids are introduced, a trial of high-dose ICS + LABA + either LTRA, theophylline, or zileuton may be considered, although this approach has not been studied in clinical trials.

Figure 18-8 Stepwise approach for managing asthma in youth 12 years of age or older and adults. (Reprinted from National Institutes of Health. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. Bethesda, MD: National Heart, Lung, and Blood Institute; 2007. NIH publication 07-4051.)

Short-Acting Inhaled β_2-Adrenergic Agonist Therapy

SHORT-ACTING INHALED β_2-AGONISTS COMPARED WITH OTHER BRONCHODILATORS

CASE 18-1, QUESTION 4: Why was a SABA selected as the bronchodilator of first choice in preference to other bronchodilators such as aminophylline or ipratropium for Q.C.?

Because of their potency and rapidity of action, short-acting inhaled β_2-agonists (SABAs) are considered the first choice for the treatment of acute asthma.[1] The bronchodilatory properties of SABAs are particularly effective in reversing early-phase asthma responses. Aminophylline (a theophylline salt) is not as efficacious and has more risks for serious adverse effects than inhaled albuterol.[1] Similarly, the bronchodilation from the anticholinergic drug ipratropium is of smaller magnitude than with inhaled SABAs.[1] However, two double-blind pediatric trials found that the sickest children had a reduced rate of hospitalization if given ipratropium with albuterol in the ED.[18,19] In one trial,[18] children with baseline FEV_1 less than 30% of predicted value had a reduced rate of admission with ipratropium, and in the other trial,[19] children with baseline PEF less than 50% had a reduced rate of hospital admission. Consequently, although early addition of inhaled ipratropium in adequate doses to SABAs will improve pulmonary function tests and reduce the rate of hospitalization in severely ill patients, Q.C.'s physician chose to use only inhaled SABAs initially because Q.C. was not severely ill.

PREFERRED ROUTES OF ADMINISTRATION

CASE 18-1, QUESTION 5: What is the preferred route of administration for short-acting bronchodilators?

It is well documented that SABAs administered by the inhaled route provide as great or greater bronchodilation with fewer systemic side effects than either the parenteral or oral routes.[1] In situations of acute bronchospasm, concerns about adequate penetration of aerosols into the bronchial tree led many clinicians to believe that the parenteral route of administration would be more effective than the inhaled route of administration. In clinical trials, however, inhaled SABAs were as effective as the standard treatment of subcutaneous epinephrine for ED treatment of acute asthma in adults and children.[1,20] Therefore, aerosolized SABAs now are considered the agents of choice for ED or hospital management of asthma.[1] β_2-Agonists should not be administered orally to treat acute episodes of severe asthma because of the slow onset of action, lower efficacy, and erratic absorption.[1]

CASE 18-1, QUESTION 6: Q.C. received albuterol by nebulization. Would metered-dose aerosol administration of the SABA have been preferred? Is the dose given by nebulization the same as that given by a metered-dose inhaler (MDI)?

Aerosols are mixtures of particles (e.g., a drug–lipid mixture) suspended in a gas.

An MDI consists of an aerosol canister and an actuation device (valve). The drug in the canister is a suspension or solution mixed with propellant. The valve controls the delivery of drug and allows the precise release of a premeasured amount of the product. A second aerosol device, the air jet nebulizer, mechanically produces a mist of drug. The drug is placed in a small volume of solute (typically 3 mL of saline) and then placed in a small reservoir (nebulizer) connected to an air source such as a small compressor pump, oxygen tank, or wall air hose. Air travels from the relatively large-diameter tubing of the air source into a pinhole-sized opening in the nebulizer. This creates a negative pressure at the site of the air entry and causes the drug solution in the bottom of the nebulizer reservoir to be drawn up through a small capillary tube where it then encounters the rapid airflow. The drug solution is forced against a small baffle that causes mechanical formation of a mist. An ultrasonic nebulizer is a type of nebulizer that uses sound waves to generate the aerosol.

Studies that compared nebulization with pressurized metered-dose aerosols in stable chronic asthma patients have shown no advantage among these methods of administration when equivalent doses are administered.[1,21] Trials comparing metered-dose aerosols of inhaled SABAs with the nebulization of those same drugs in acute asthma also have shown no significant advantage for the nebulization method of administration when the metered-dose aerosolized administration was carefully supervised by experienced personnel and a spacer device was used.[22–24] However, in some younger acutely ill children, it is difficult (even with supervision) to administer an effective SABA with a metered-dose canister. Because many patients and clinicians perceive that nebulizers provide more intensive therapy, it often is important psychologically to give at least the first dose of a SABA via a nebulizer. Thereafter, it is more cost effective to use the therapeutically equivalent MDI plus spacer.[22]

The dose ratio for SABAs delivered by MDI plus spacer versus nebulizer has varied in the literature. For children with mild acute asthma, two puffs of albuterol MDI attached to a spacer were not different from 6 to 10 puffs of albuterol or via nebulizer 0.15 mg/kg.[23] In one double-blind trial in children with a severe exacerbation, investigators used a dose ratio of 1:5 (i.e., albuterol MDI spacer 1 mg [10 puffs]: nebulized albuterol 5 mg).[24] Nebulization of albuterol with compressed air or, preferably, oxygen was the preferred method of administration for Q.C. initially.

Dosing

CASE 18-1, QUESTION 7: Starting 20 minutes after the first albuterol dose, two more doses of 2.5 mg of albuterol were administered by nebulizer every 20 minutes during the next 40 minutes. After three treatments, Q.C.'s breath sounds became increasingly clear. She was no longer in distress and could speak in complete sentences. Her PEF was now 70% of predicted, her Sa_{O_2} was 97% on room air, and discharge to home was planned. Were the dose and dosing interval of albuterol appropriate for Q.C.?

Schuh et al.[25] demonstrated that a higher-dose albuterol regimen (0.15 mg/kg vs.

0.05 mg/kg every 20 minutes) produced significantly greater improvement with no greater incidence of adverse effects. Schuh et al.[26] subsequently reported greater efficacy of albuterol in a dose of 0.3 mg/kg (up to 10 mg) hourly compared with a dose of 0.15 mg/kg (up to 5 mg) hourly in children. The larger dose was tolerated as well as the 0.15 mg/kg dose. Therefore, Q.C.'s albuterol regimen of 2.5 mg (0.13 mg/kg) nebulized 20 minutes for 40 minutes subsequent to her first dose of aerosolized albuterol could have been even more aggressive but was appropriate. Figure 18-9 provides treatment guidelines for the ED and hospital management of asthma.[1] Drug dosing recommendations are listed in EPR-3.[1] In addition to EPR-3, a review of the emergency treatment of asthma has recently been published.[27]

Comparison of Short-Acting Inhaled β_2-Agonists

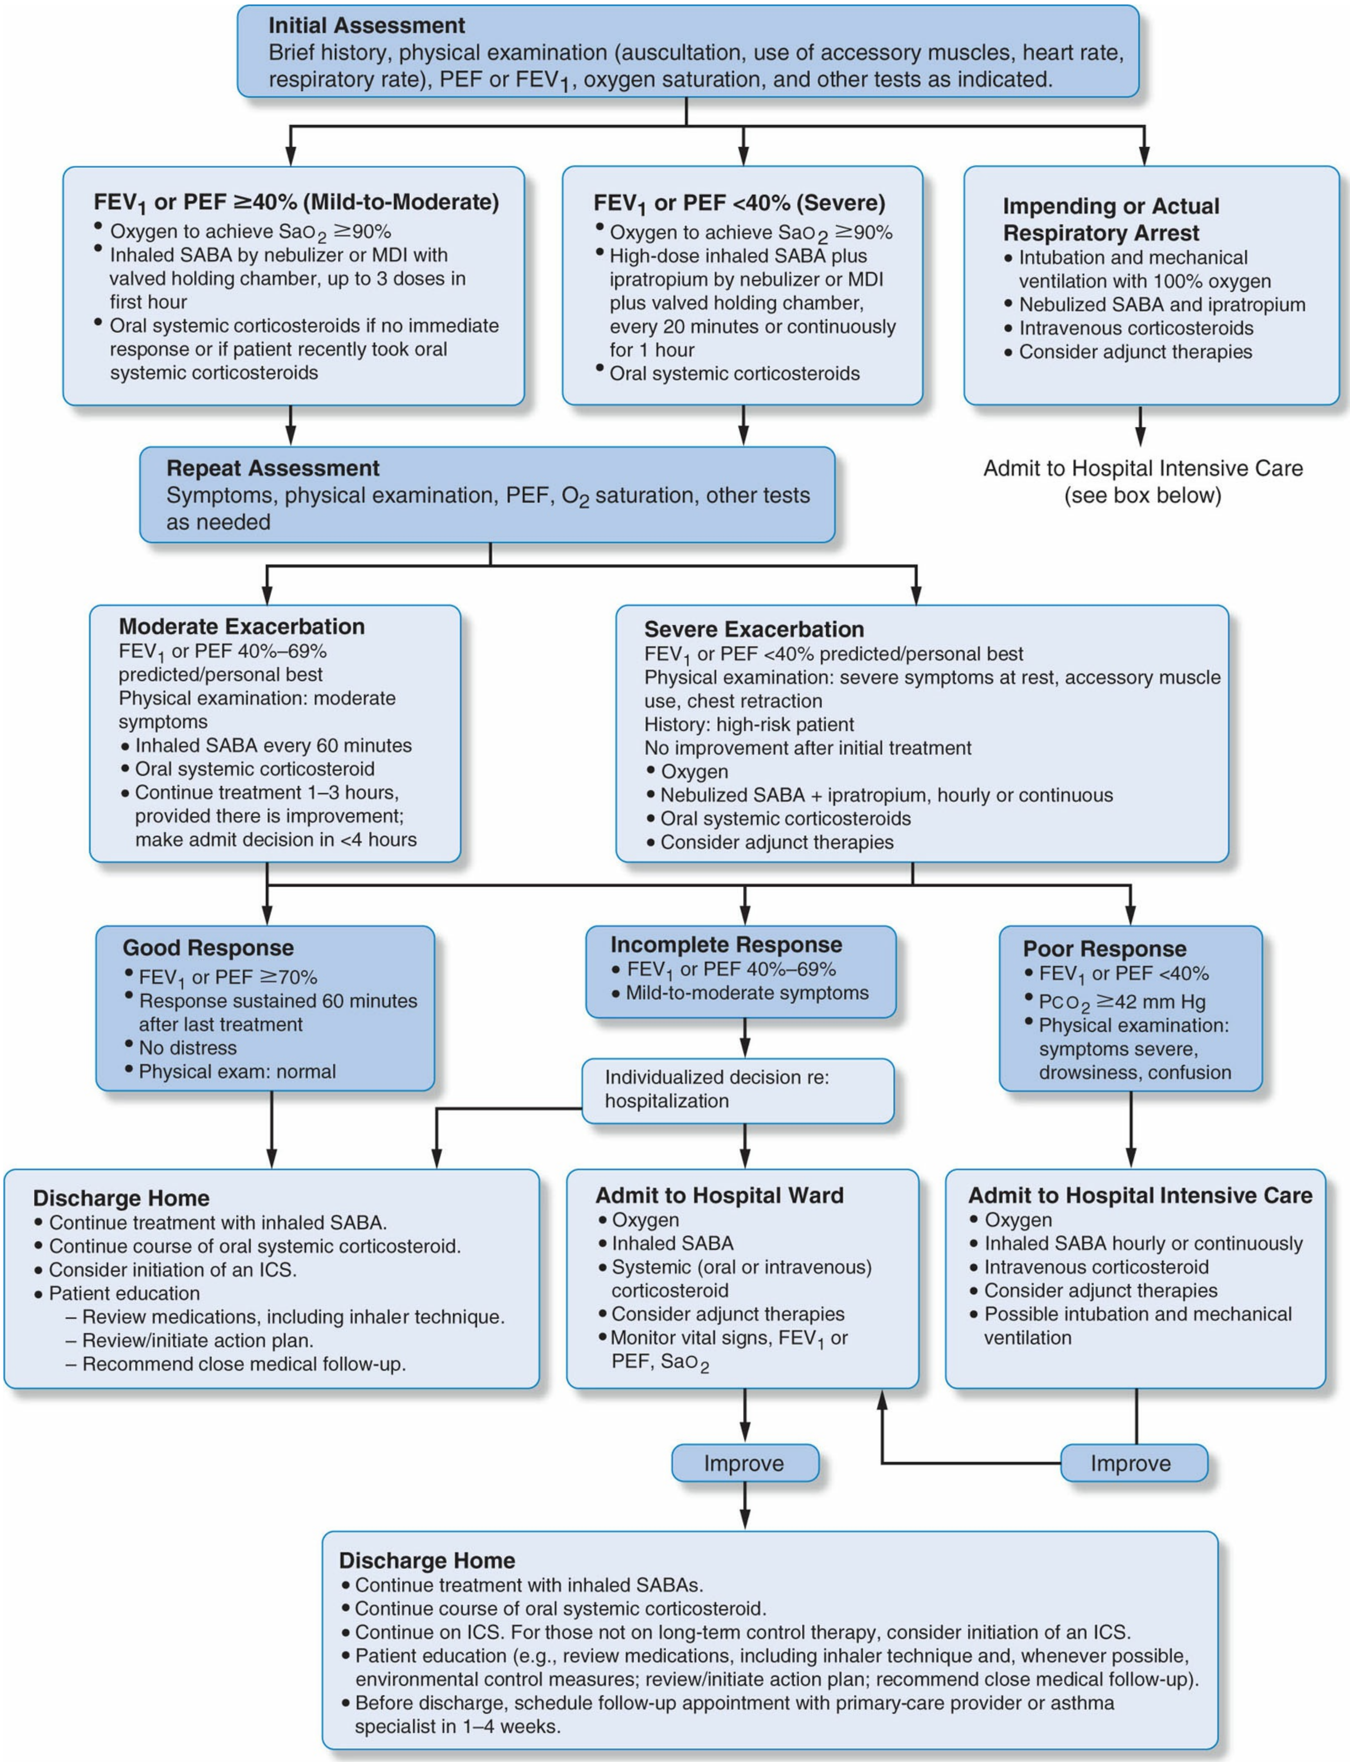
CASE 18-1, QUESTION 8: Would another SABA have been more effective in the initial therapy of Q.C.?

SABAs (e.g., albuterol) are preferred over nonspecific agonists (e.g., isoproterenol). Long-acting β_2-agonists (e.g., salmeterol) are not indicated for treatment of asthma in the ED. Levalbuterol (R-albuterol) is a single-isomer, higher-potency drug but does not offer any clinically significant advantages (i.e., improved outcomes) in most patients versus racemic albuterol to justify its higher cost.[1]

SYSTEMIC CORTICOSTEROIDS IN THE EMERGENCY DEPARTMENT FOR CHILDREN

CASE 18-1, QUESTION 9: Should Q.C. receive corticosteroid therapy as part of her ED management?

Yes. Because asthma is primarily an inflammatory airway disease, the degree of inflammation associated with Q.C.'s current exacerbation should be considered. Per EPR-3[1] (Fig. 18-9) if there is not an immediate response to inhaled β_2-agonist therapy, oral systemic corticosteroids should be administered (refer to further discussion of this subject in Case 18-2, Questions 4 and 5). Furthermore, if Q.C. had a peak flow meter at home, earlier objective detection of the development of this exacerbation might have prevented an ED visit. When the PEF is in the red zone (<50% of personal best) and poorly responsive to SABAs, early intervention with oral corticosteroids is associated with a reduction in ED visits[1] (Fig. 18-10); refer to the Outcomes section at the end of the chapter). Q.C. and her parents should also understand that if respiratory distress is severe and nonresponsive to treatment, they should proceed to an ED or call 9-1-1. Finally, before going home from the ED, Q.C. and her parents should receive some basic education regarding asthma and its acute and long-term management. It is important to follow up with more detailed education during future clinic visits. According to EPR-3,[1] Q.C. should receive a short course of systemic corticosteroids as part of her discharge plan, thereby reducing her risk of re-exacerbation. Typically, oral prednisolone solution at a dose of 1 to 2 mg/kg in daily or divided doses twice daily is given for approximately 5 to 7 days. Although this regimen is very effective, to improve adherence several studies have examined shorter (1- to 2-day) courses of oral or intramuscular dexamethasone and have found similar results when compared with usual regimens of oral prednisone or prednisolone.[28–30]



Initial Assessment
Brief history, physical examination (auscultation, use of accessory muscles, heart rate, respiratory rate), PEF or FEV_1, oxygen saturation, and other tests as indicated.

FEV_1 or PEF ≥40% (Mild-to-Moderate)
- Oxygen to achieve SaO_2 ≥90%
- Inhaled SABA by nebulizer or MDI with valved holding chamber, up to 3 doses in first hour
- Oral systemic corticosteroids if no immediate response or if patient recently took oral systemic corticosteroids

FEV_1 or PEF <40% (Severe)
- Oxygen to achieve SaO_2 ≥90%
- High-dose inhaled SABA plus ipratropium by nebulizer or MDI plus valved holding chamber, every 20 minutes or continuously for 1 hour
- Oral systemic corticosteroids

Impending or Actual Respiratory Arrest
- Intubation and mechanical ventilation with 100% oxygen
- Nebulized SABA and ipratropium
- Intravenous corticosteroids
- Consider adjunct therapies

Admit to Hospital Intensive Care (see box below)

Repeat Assessment
Symptoms, physical examination, PEF, O_2 saturation, other tests as needed

Moderate Exacerbation
FEV_1 or PEF 40%–69% predicted/personal best
Physical examination: moderate symptoms
- Inhaled SABA every 60 minutes
- Oral systemic corticosteroid
- Continue treatment 1–3 hours, provided there is improvement; make admit decision in <4 hours

Severe Exacerbation
FEV_1 or PEF <40% predicted/personal best
Physical examination: severe symptoms at rest, accessory muscle use, chest retraction
History: high-risk patient
No improvement after initial treatment
- Oxygen
- Nebulized SABA + ipratropium, hourly or continuous
- Oral systemic corticosteroids
- Consider adjunct therapies

Good Response
- FEV_1 or PEF ≥70%
- Response sustained 60 minutes after last treatment
- No distress
- Physical exam: normal

Incomplete Response
- FEV_1 or PEF 40%–69%
- Mild-to-moderate symptoms

Individualized decision re: hospitalization

Poor Response
- FEV_1 or PEF <40%
- PCO_2 ≥42 mm Hg
- Physical examination: symptoms severe, drowsiness, confusion

Discharge Home
- Continue treatment with inhaled SABA.
- Continue course of oral systemic corticosteroid.
- Consider initiation of an ICS.
- Patient education
  - – Review medications, including inhaler technique.
  - – Review/initiate action plan.
  - – Recommend close medical follow-up.

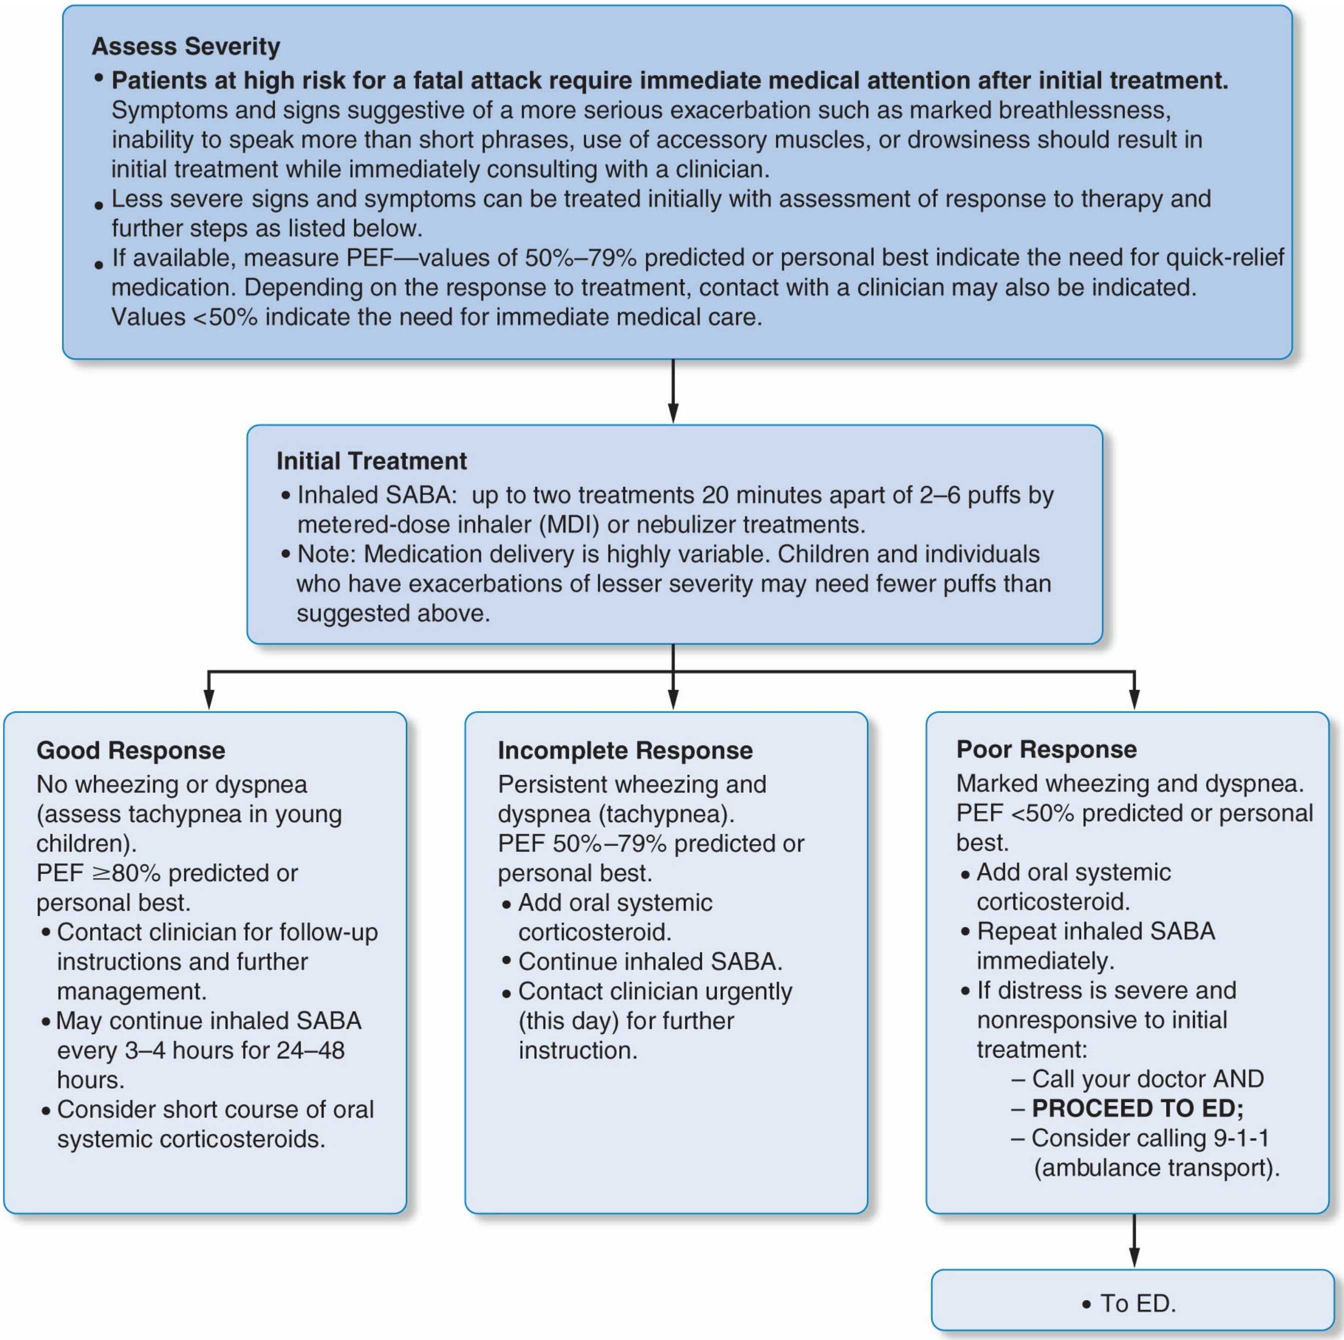
Admit to Hospital Ward
- Oxygen
- Inhaled SABA
- Systemic (oral or intravenous) corticosteroid
- Consider adjunct therapies
- Monitor vital signs, FEV_1 or PEF, SaO_2

Admit to Hospital Intensive Care
- Oxygen
- Inhaled SABA hourly or continuously
- Intravenous corticosteroid
- Consider adjunct therapies
- Possible intubation and mechanical ventilation

Discharge Home
- Continue treatment with inhaled SABAs.
- Continue course of oral systemic corticosteroid.
- Continue on ICS. For those not on long-term control therapy, consider initiation of an ICS.
- Patient education (e.g., review medications, including inhaler technique and, whenever possible, environmental control measures; review/initiate action plan; recommend close medical follow-up).
- Before discharge, schedule follow-up appointment with primary-care provider or asthma specialist in 1–4 weeks.

Figure 18-9 Management of asthma exacerbations: emergency department and hospital-based care. FEV_1, forced expiratory volume in 1 second; ICS, inhaled corticosteroid; MDI, metered-dose inhaler; Pco_2, partial pressure of carbon dioxide; PEF, peak expiratory flow; SABA, short-acting β_2-agonist; Sao_2, arterial oxygen saturation. NIH publication 07-

4051.)



Assess Severity
• Patients at high risk for a fatal attack require immediate medical attention after initial treatment. Symptoms and signs suggestive of a more serious exacerbation such as marked breathlessness, inability to speak more than short phrases, use of accessory muscles, or drowsiness should result in initial treatment while immediately consulting with a clinician.
• Less severe signs and symptoms can be treated initially with assessment of response to therapy and further steps as listed below.
• If available, measure PEF—values of 50%–79% predicted or personal best indicate the need for quick-relief medication. Depending on the response to treatment, contact with a clinician may also be indicated. Values <50% indicate the need for immediate medical care.
Initial Treatment
• Inhaled SABA: up to two treatments 20 minutes apart of 2–6 puffs by metered-dose inhaler (MDI) or nebulizer treatments.
• Note: Medication delivery is highly variable. Children and individuals who have exacerbations of lesser severity may need fewer puffs than suggested above.
Good Response
No wheezing or dyspnea (assess tachypnea in young children).
PEF ≥80% predicted or personal best.
• Contact clinician for follow-up instructions and further management.
• May continue inhaled SABA every 3–4 hours for 24–48 hours.
• Consider short course of oral systemic corticosteroids.
Incomplete Response
Persistent wheezing and dyspnea (tachypnea).
PEF 50%–79% predicted or personal best.
• Add oral systemic corticosteroid.
• Continue inhaled SABA.
• Contact clinician urgently (this day) for further instruction.
Poor Response
Marked wheezing and dyspnea.
PEF <50% predicted or personal best.
• Add oral systemic corticosteroid.
• Repeat inhaled SABA immediately.
• If distress is severe and nonresponsive to initial treatment:
– Call your doctor AND
– PROCEED TO ED;
– Consider calling 9-1-1 (ambulance transport).
• To ED.

Figure 18-10 Management of asthma exacerbations: home treatment. ED, emergency department; MDI, metered-dose inhaler; PEF, peak expiratory flow; SABA, short-acting β_2-agonist. (Adapted from National Institutes of Health. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. Bethesda, MD: National Heart, Lung, and Blood Institute; 2007. NIH publication 07-4051.)

Adverse Effects

CASE 18-2

QUESTION 1: H.T., a 45-year-old, 91-kg man with a long history of severe-persistent asthma, presents to the

ED with severe dyspnea and wheezing. He is able to say only two or three words without taking a breath. He has been taking four inhalations of beclomethasone hydrofluoroalkane (HFA; 80 mcg/puff) twice daily (BID) and two inhalations of albuterol MDI 4 times a day (QID) as needed (PRN) on a chronic basis. H.T. ran out of beclomethasone a week ago; since then, he has been using his albuterol MDI with increasing frequency up to every 3 hours on the day before admission. He is a lifelong nonsmoker. His FEV_1 was 25% of the predicted value for his age and height, and his SaO_2 was 82%. Vital signs are as follows:

Heart rate, 130 beats/minute
RR, 30/minute
Pulsus paradoxus, 18 mm Hg
BP, 130/90 mm Hg

ABGs on room air were as follows:

pH, 7.40
Pao_2, 55 mm Hg
$Paco_2$, 40 mm Hg
Serum electrolyte concentrations were as follows:
Sodium (Na), 140 mEq/L
Potassium (K), 3.9 mEq/L
Chloride (Cl), 105 mEq/L

Because of the severity of the obstruction, H.T. was monitored with an electrocardiogram that showed sinus tachycardia with occasional premature ventricular contractions. Albuterol 5.0 mg and ipratropium 0.5 mg were administered by nebulization with minimal improvement. H.T. then was started on O_2 at 4 L/minute by nasal cannula, followed in 20 minutes by a second dose of albuterol 5.0 mg plus ipratropium 0.5 mg via nebulizer. Subsequently, H.T.'s heart rate increased to 140 beats/minute, and he complained of palpitations and shakiness. His PEF was now 25% of personal best. Laboratory values were as follows:

pH, 7.39
Pao_2, 60 mm Hg
$Paco_2$, 42 mm Hg
Na, 138 mEq/L
K, 3.5 mEq/L

What adverse effects experienced by H.T. are consistent with systemic β_2-agonist administration?

H.T. experienced palpitations, which may have been caused by the widening of his pulse pressure from vasodilation. Albuterol and all other β-agonists are cardiac stimulants that may cause tachycardia and, very rarely, arrhythmias. Because they are relatively β_2-specific, the cardiac effects are more prominent with systemic administration (as opposed to inhalation) and at higher dosages. However, other causes of cardiac effects must also be considered, such as hypoxemia, which is also a potent stimulus for cardiac arrhythmias. Therefore, H.T.'s tachycardia may have been caused by the β_2-agonist, by the worsening of his airway obstruction (as reflected in the increase in $Paco_2$), or by both of these variables.

The decrease in the serum potassium concentration from 3.9 to 3.5 mEq/L could be attributed to β_2-adrenergic activation of the Na^+-K^+ pump and subsequent transport of potassium intracellularly.[31,32] However, at usual doses, aerosolized albuterol causes relatively little effect on serum potassium. The effects may be more noticeable with high doses of inhaled albuterol.[33] A β_2-adrenergic-mediated increase in glucose and insulin secretion also can contribute to the intracellular shift of potassium.[34] The shakiness (tremors) experienced by H.T. probably can be attributed to β_2-receptor stimulation of skeletal muscle. Again, this effect is most prominent with oral or parenteral administration, but some patients are very sensitive to even small doses of inhaled SABAs.

β-ADRENERGIC AGONIST SUBSENSITIVITY

CASE 18-2, QUESTION 2: Why did H.T. fail to respond to the initial therapy? Could tolerance to the β_2-agonists have contributed?

Although tolerance to systemic effects of β_2-agonists (e.g., tremor, sleep disturbances) is documented, tolerance to the airway response does not occur to a clinically significant extent.[33,34] Even with long-term use, the intensity of response to β_2-agonists is retained (i.e., the maximal percent increase in pulmonary function), but the duration of response with each dose may shorten. Such an effect is unlikely with intermittent use but may occur in patients who routinely use large, multiple doses daily. Possible explanations for this variability include downregulation of receptors, disease progression, or true drug tolerance. The exact contribution of each is not known. Therefore, H.T.'s failure to respond to the initial therapy most likely is attributable to the severity of his airway obstruction. H.T.'s history of severe chronic asthma, the slow progression of this attack, and the lack of response to his inhaled β_2-agonist also are largely owing to a significant inflammatory component to this attack. Thus, bronchodilators would not be expected to immediately reverse the airway obstruction in H.T. It would be difficult to attribute his lack of initial response to therapy to β_2-adrenergic subsensitivity. In addition, it is not likely that β_2-adrenergic receptor polymorphisms could account for H.T.'s initial lack of response.[34] Although polymorphic variations are documented to be relevant in some stable patients,[1] further study is needed to establish clinical relevance.

CASE 18-2, QUESTION 3: Repeat measurements of PEF and ABGs indicate continued significant bronchial obstruction. What should be the next step in H.T.'s therapy?

H.T. received initial therapy with a combination of inhaled SABAs and ipratropium. He should receive a third dose of albuterol 5.0 mg plus ipratropium 0.5 mg 20 minutes after the second dose. Because of the severity of his exacerbation, he should then receive albuterol 15 mg/hour by continuous nebulization with close monitoring of his cardiac status. H.T.'s PEF also should be monitored.

SHORT-ACTING INHALED β-AGONISTS IN COMBINATION WITH CORTICOSTEROIDS

CASE 18-2, QUESTION 4: Are systemic corticosteroids appropriate for H.T.? When can a response be expected?

Corticosteroids have potent anti-inflammatory activity and are definitely indicated in H.T.[1,35] In patients like H.T. with acute asthma, corticosteroids decrease airway inflammation[36–39] and increase the response to β_2-selective agonists.[1,36] Corticosteroids are not smooth muscle relaxants (i.e., not bronchodilators); however, they can relieve bronchial obstruction by improving the responsiveness of β_2-receptors and by inhibiting numerous phases of the inflammatory response (e.g., cytokine production, neutrophil and eosinophil chemotaxis and migration, and release of inflammatory mediators).[1]

The anti-inflammatory activity of corticosteroids is delayed for about 4 to 6 hours after the dose has been administered. Corticosteroid-induced restoration of responsiveness to endogenous catecholamines and exogenous β_2-agonists, however, occurs within 1 hour of administration of the corticosteroid in severe, chronic, stable asthmatic patients.[36] Significant improvement in objective measures (e.g., FEV_1) generally occurs 12 hours after administration.[38] Consequently, EPR-3[1] advocates early initiation of corticosteroids in cases of acute severe asthma. Corticosteroids also hasten the recovery of acute exacerbations of asthma[35,40–43] and decrease the need for hospitalization if given early in the initial management of acute asthma in the ED.[38]

On the basis of his initial presentation, H.T. should be started on systemic corticosteroid therapy immediately in the ED (Fig. 18-9). Preferably, oral corticosteroids would have been started at home before H.T.'s exacerbation escalated to this degree of severity (Fig. 18-10).

CASE 18-2, QUESTION 5: What would be an appropriate dosing regimen of corticosteroids for H.T. in the ED? Would the dose and route be the same if he were hospitalized?

Doses of corticosteroids used to treat acute asthma are largely empiric. Studies comparing very high dosages (e.g., intravenous [IV] methylprednisolone 125 mg every 6 hours in an adult) versus moderate dosages (40 mg every 6 hours) have shown no advantage with very high dosages.[1,44,45] In addition, oral therapy is as efficacious as the IV route.[1,44,45] Dosing recommendations for systemic corticosteroids in the management of asthma exacerbations in the ED or hospital are listed in EPR-3.[1] Higher corticosteroid dosages may be considered in patients with impending respiratory failure. When patients cannot take oral medication, IV methylprednisolone is preferred over hydrocortisone in patients with heart disease or fluid retention or when high dosages of corticosteroids are used; this is because it has less mineralocorticoid activity.

For patients who require IV corticosteroid therapy, the dosage can usually be reduced rapidly to 60 to 80 mg/day for adults (1–2 mg/kg/day for children) because the condition improves (usually after 48–72 hours). On discharge from the hospital, EPR-3[1] recommends, for example, prednisone 40 to 80 mg/day in one or two doses for 3 to 10 days. Although some clinicians may prescribe a tapering regimen, no taper is necessary in this situation. On the other hand, if the patient required long-term oral corticosteroid therapy before hospitalization, tapering the dose to the preadmission dosage is prudent. For patients who are discharged from the ED, up to 7 days of prednisone therapy usually is sufficient.

CASE 18-2, QUESTION 6: H.T. was given one dose of 60 mg of methylprednisolone (Solu-Medrol) IV and three doses of albuterol 5 mg/ipratropium 0.5 mg by nebulizer every 20 minutes in the ED). H.T. claimed slight subjective improvement after this therapy; yet, expiratory wheezes still were audible, and he still was using his accessory muscles for ventilatory efforts. His PEF improved only to 35% of predicted, and a repeat ABG measurement showed a $Paco_2$ of 40 mm Hg. What should be done at this time?

H.T. still is significantly obstructed despite intensive therapy in the ED. As a result, he should be admitted to the intensive care unit (ICU), where he can be monitored closely.

Respiratory Failure

SIGNS AND SYMPTOMS

CASE 18-2, QUESTION 7: What would be the best method of assessing the adequacy of therapy in H.T.? What are the signs of impending respiratory failure?

When patients continually must expand their chest wall with high lung volumes for a prolonged period, respiratory muscle fatigue may ensue, resulting in a decreased ventilatory effort. Clinical signs of impending respiratory failure include increased heart rate, decreased breath sounds, agitation from worsening hypoxia, or lethargy from increased CO_2 retention. These clinical signs and symptoms are relatively nonspecific and are affected by many variables. Thus, they should not be used to detect impending respiratory failure.

The best way to assess therapy is to monitor ABGs. The Pao_2 component of an ABG determination is not very helpful because of $\dot{V}/\dot{Q}$ mismatching and the administration of oxygen. The $Paco_2$ is the best indicator of hypoventilation in acute asthma[1]; however, there is no single value for $Paco_2$ that indicates impending respiratory failure, because different $Paco_2$ values are acceptable under different clinical circumstances. A $Paco_2$ of 55 mm Hg 1 to 2 hours after intensive bronchodilator therapy or an increase in $Paco_2$ of 5 to 10 mm Hg/hour during aggressive therapy is an ominous sign. The fact that H.T.'s $Paco_2$ is not rising with therapy is a good sign.

β_2-AGONISTS AND OTHER POTENTIAL THERAPIES

CASE 18-2, QUESTION 8: H.T. initially received three doses of albuterol 5 mg/ipratropium 0.5 mg by nebulizer every 20 minutes in the ED. He has also received IV methylprednisolone 60 mg. Would the IV administration of a β-agonist be indicated in H.T. at this time? What are other potential therapies in H.T.?

Although the use of IV β-agonists for asthmatic patients in the ICU formerly was advocated, current standards of care discourage the use of these agents.[1] H.T.'s response to inhaled albuterol also suggest that IV β-agonists are inappropriate at this time. Because standard therapies already administered were not sufficient, IV magnesium sulfate may benefit severely ill patients like H.T.[1,46] Recent research suggests that nebulized isotonic magnesium sulfate is a valuable adjunctive therapy to inhaled albuterol in the treatment of severe asthma exacerbations.[47] Further, heliox (a mixture of helium and oxygen) may also add benefit.[1,48]

THEOPHYLLINE

CASE 18-2, QUESTION 9: Intravenous theophylline is being considered for H.T. Is theophylline likely to be of benefit in impending respiratory failure?

Studies on the treatment of acute asthma in the ED have failed to demonstrate any benefit of adding theophylline to optimal, inhaled β-agonist therapy,[1,49] and the EPR-3 does not recommended this practice.[1] Furthermore, several double-blind, randomized, placebo-controlled studies have demonstrated that theophylline does not add benefit to intensive therapy with inhaled β_2-agonists and systemic corticosteroids in hospitalized adults[50] or children[51–54] who fail to respond to aggressive ED therapy with SABAs. Note in Figure 18-9 from EPR-3[1] that theophylline is not recommended for routine management of hospitalized patients with asthma. Although one study[55] has shown a slight benefit of theophylline in hospitalized adult asthmatic patients, one of the authors of that study has since noted that if adequate doses of SABAs and systemic corticosteroids are used, theophylline is probably not routinely indicated.[56] Although further research is needed to establish whether theophylline may add benefit to hospitalized adult patients who have impending respiratory failure, routine use of theophylline in hospitalized asthmatic patients no longer is justified.

Limited evidence suggests a potential benefit of theophylline for some pediatric patients in the ICU who have impending respiratory failure.[57] However, more recent study does not show any benefit and suggests longer ICU stays and time for symptom improvement.[58] EPR-3 does not recommend the use of theophylline in the hospital.[1] H.T.'s clinicians decide not to use theophylline. If a clinician decides to use theophylline in this setting, a current pharmacokinetics text should be consulted to help ensure safe and effective dosing and monitoring.[59]

Response to Therapy

CASE 18-2, QUESTION 10: H.T. has continued to improve slowly during the last 72 hours. The nebulizer treatments with albuterol are now administered every 4 hours, and he is taking oral prednisone 80 mg/day in two divided doses. PEF measurements taken before and after the last albuterol treatment were 65% of predicted and 80% of predicted, respectively. Is H.T.'s long duration of recovery unusual?

No. In a patient such as H.T., whose condition progressively deteriorated during a long period, a slow reversal should be expected. The prolonged deterioration reflects an increasing inflammatory response in the lung. These patients require prolonged, intensive bronchodilator and anti-inflammatory therapy before maximal improvement is noted in pulmonary function tests. Thus, H.T. should continue to receive systemic corticosteroids for approximately 10 days after such a severe acute exacerbation of asthma.[1]

Adverse Effects of Short-Term Corticosteroid Therapy

CASE 18-2, QUESTION 11: H.T. has been taking corticosteroids for a total of 6 days. Long-term corticosteroid use is associated with many adverse effects (e.g., adrenal suppression, osteoporosis, cataracts). What adverse effects are related to short-term corticosteroid use?

Short courses of daily corticosteroids are usually associated with minor side effects.[35,40–43] Facial flushing, appetite stimulation, gastrointestinal irritation, headache, and mood changes ranging from a mere sense of well-being to overt toxic psychosis are the most commonly encountered adverse effects of short-term corticosteroid therapy. Acne can be exacerbated in patients susceptible to this skin problem, and weight gain also can occur because of sodium and fluid retention. In addition, hyperglycemia, leukocytosis, and hypokalemia are possible. All of these problems are transient and will disappear with time after the corticosteroids are discontinued. These short-term adverse effects are less common when small corticosteroid doses are used; however, corticosteroid doses must be adequate to prevent disease exacerbation. The minor risks of short-term use are far outweighed by the marked benefits.

Overuse of Short-Acting Inhaled β-Agonists

CASE 18-2, QUESTION 12: H.T.'s history of increased use of his SABA inhaler during the early stages of this asthma attack suggests improper use of this medication. What are the risks from overuse of β_2-agonists?

The overuse of SABAs as a possible risk factor for asthma death has been debated for decades.[60] Because most deaths attributable to asthma occur outside the hospital setting before the patient can reach medical assistance, the primary cause of death in asthma most probably is an underestimation of the severity of the asthma attack by the patient and delay in seeking medical help. Overuse of quick reliever medication suggests inadequate asthma control and can lead to fatal asthma.[1,60]

The frequency of as-needed doses of albuterol is a good marker of the adequacy of inhaled anti-inflammatory therapy and environmental control measures. For example, if the patient needs the SABA more than 2 or 3 times a day, the clinician should reassess environmental control, increase the dose of inhaled anti-inflammatory therapy, or add other controller agents per EPR-3.[1]

Patients should be instructed verbally and in writing regarding the proper use of their inhalers during acute attacks and in recognizing when it is necessary to seek medical assistance (Fig. 18-10) Patients can continue using their short-acting β-agonist inhalers on an as-needed basis until they reach medical care. H.T. should be considered at high risk because of the severity of his latest attack and should be given oral corticosteroids to self-administer at the first sign of significant deterioration.[1] In addition, H.T. should have a home peak flow meter so that he can objectively determine the severity of his attacks. Finally, the β_2-agonist controversy does not extend to use of high dosages in the acute-care setting. High dosages are essential in the ED and hospital and, as discussed previously, usually are tolerated very well.

CHRONIC ASTHMA

Classification of Severity

CASE 18-3

QUESTION 1: B.C. is a 3-year-old, 16-kg boy with a 1.5-year history of recurrent wheezing 3 days per week and nocturnal awakenings 4 times per month. His medications include albuterol syrup (2 mg/5 mL) one teaspoonful 3 times a day (TID) and albuterol metered-dose aerosol inhalation QID PRN for wheezing. B.C. demonstrates the use of the inhaler with his mother's assistance. The mother holds the inhaler in B.C.'s mouth and actuates it at the end of a deep inhalation. B.C.'s mother tells the clinician that he appears "jittery" after taking albuterol syrup. What is the first step in deciding how to improve B.C.'s long-term drug therapy?

While keeping in mind the goals of therapy defined by the NIH guidelines (EPR-3),[1] the first step here is to classify B.C.'s asthma severity (refer to Table 18-1) for infants to age 4 years). Because B.C. has symptoms 3 days per week and 4 nights per month, he should be classified as "moderate persistent." Note that the presence of even one of the features of severity places the patient in that category.

Selection of Appropriate Initial Long-Term Therapy

CASE 18-3, QUESTION 2: What would be a reasonable initial regimen for B.C.?

Because B.C.'s asthma is classified as moderate persistent, the clinician is now in a position to select appropriate long-term therapy. Using EPR-3[1] for very young children (Fig. 18-6), low- or medium-dose inhaled corticosteroids (ICS) with an as-needed SABA would be the choice for B.C.[1] In considering this decision, EPR-3 Figure 18-6 has "Notes" below the treatment steps. For example, it is noted that Step 2 (low-dose ICS) is preferred in this very young age group based on the strongest evidence (Evidence A). It is further noted that other recommendations are based on expert opinion and extrapolation from studies in older pediatric patients.[1] EPR-3 suggests an initial trial of low-dose ICS in very young children who have not previously been treated with ICS. B.C. could receive low-dose ICS treatments via nebulizer (budesonide) or MDI plus a spacer. Most children aged 3 years or younger cannot use dry powder inhalers because of inability to generate sufficient peak inspiratory flow (PIF). Because B.C. matures, he may be able to use some dry powder inhalers (e.g., Diskus). Because oral β_2-agonists are not recommended by EPR-3 and the albuterol syrup was not well tolerated, they should not be used. If concurrent inhaled albuterol is administered correctly, oral albuterol is not needed and would only be expected to add adverse effects. B.C.'s mother must be educated about asthma, its treatment, and the appropriate use of medications (e.g., proper use of inhaler devices; refer to Case 18-13, Questions 1 and 2).

CASE 18-3, QUESTION 3: It is anticipated that because of his young age, B.C. will find it difficult to use an MDI. What alternative inhalation devices are reasonable?

Children younger than 5 years of age generally have a difficult time coordinating the use of standard MDIs; therefore, the ICS and SABA should be administered by another mode of delivery. For example, the as-needed β_2-agonist and scheduled ICS could

---

be administered with an inhalational aid ("spacer" or valved holding chamber), which is connected to an MDI. A nebulized corticosteroid preparation (budesonide) is available for very young children.[61] Inhalation aids significantly improve the efficacy of medications that are administered by MDI in very young children or other patients who are unable to coordinate the plain inhalers correctly.[1,62–64] The AeroChamber is a widely used valved holding chamber (the medication stays in the chamber for a few seconds until the patient inhales slowly and the inhalation valve opens). Studies have shown that many children as young as 2 and 3 years of age can use MDIs with spacer devices by modeling after a parent.[62,63] Spacer devices with face masks are required for some young children. Extender device-assisted delivery of aerosolized medications is as effective as nebulization in the home management of chronic severe asthma[65] and even in the ED treatment of asthma in children.[1,22–24,64] AeroChamber is an example of a device that contains a flow indicator whistle that sounds if the patient inhales rapidly. This whistle is particularly effective in teaching the patient the appropriate slow inhalation technique. As a 3-year-old, B.C. may not need a spacer with a face mask, but the clinician should verify correct use of the device by observation of the patient's or caregiver's administration technique.

Alternatively, the ICS could be administered to selected children by using a breath-activated dry powder inhaler (e.g., budesonide [Pulmicort Flexhaler] or fluticasone [combined with salmeterol in Advair Diskus]). In young children, the Diskus has the advantage of requiring a lower PIF than Flexhaler, and it has been used successfully in children as young as 4 years of age.[66] Another option is the Twisthaler used for delivery of mometasone (Asmanex), but it is approved for children 4 years of age and older.

Many pediatricians may choose a nebulizer to administer SABAs to a 3-year-old child. This method is certainly acceptable and very common, but it takes longer to administer the medication (about 15 minutes), and the device must be properly cleaned and maintained. Because B.C. recently turned 3 years old, therapy should be initiated with nebulized budesonide (Pulmicort Respules) in a low dose of 0.25 mg BID. As mentioned previously, EPR-3[1] suggests an initial trial of low-dose ICS in very young children who have not previously been treated with ICS. The plan is to switch B.C. to a dry powder inhaler or MDI spacer in 12 months, as soon as he and his caregiver can demonstrate correct use. B.C.'s clinician should assess the response to low-dose budesonide in 4 weeks. Therapy can be stepped up if necessary and subsequently stepped down in the coming months, if possible, so that optimal asthma control is achieved at the lowest ICS dose possible.

CASE 18-3, QUESTION 4: B.C.'s parents are wary of their son taking corticosteroids on a continual basis after having read about serious side effects attributed to corticosteroids on the Internet. How should the parents be counseled?

Corticosteroids reach the systemic circulation minimally via inhalation in part because they are largely inactivated through first-pass hepatic metabolism. However, a dose-dependent response is evident, and clinically significant adverse events resulting from systemic exposure can occur, albeit more commonly with doses at the high end of the range. Long-term studies in pediatric patients have examined the effects of ICS on growth reduction, bone density, and adrenal suppression.[1,67]

Although ICS can cause a mild and temporary reduction in growth velocity, final height attained in adulthood appears to be within normal limits.[1,67] Bone density and risk of fractures have not been found in the majority of investigations to be affected by ICS.[1] Although a measurable reduction in serum and urinary cortisol levels is not an uncommon finding in studies of ICS, clinically significant adrenal insufficiency solely caused by ICS is rare, although again it is more likely to occur with high doses.[1,67] In summary, these adverse effects are generally of minimal clinical significance, with the benefits of well-controlled asthma far outweighing the risks.

The most common local side effect with ICS therapy is oropharyngeal candidiasis (thrush), but this problem is rare with any delivery system. With MDIs, it can be further minimized by use of a spacer device. Rinsing the mouth with water after use of any ICS is also recommended. Another possible local side effect is hoarseness (dysphonia), and spacers may not effectively reduce this problem.[68] Dry powder devices (e.g., Flexhaler) may have less dysphonia associated with their use, but further study is required to verify this.[68]

Seasonal Asthma

CASE 18-4

QUESTION 1: C.V., a 33-year-old woman, presents to the clinic with a history of asthma and seasonal allergic rhinitis (hay fever) each spring but not the rest of the year. She describes her asthma as “mild” and intermittent. Except during springtime, her daytime symptoms occur less than once per week, and she does not have nocturnal symptoms. Each spring, however, these symptoms worsen, and she requires her albuterol inhaler (her only asthma medication) TID or QID every day. During springtime, she takes a nonprescription antihistamine, which offers some relief. How can C.V.’s management be improved?

C.V. appears to have intermittent asthma during most of the year but converts to moderate-persistent asthma combined with worsening rhinitis symptoms in the springtime. This syndrome is consistent with a diagnosis of seasonal asthma and allergic rhinitis. Although as-needed albuterol is appropriate most of the year for C.V., she needs anti-inflammatory therapy during the spring.[1] Therapy to reduce airway inflammation should begin before the onset of tree and grass pollen season and continue throughout the spring (e.g., 3 months). Per the NIH guidelines, an excellent treatment option for C.V. is low-dose ICS combined with a long-acting inhaled β_2-agonist (LABA). Monotherapy with medium-dose ICS would also be an acceptable therapy. Not only are the causes and pathophysiology of allergic rhinitis and allergic asthma similar, poorly controlled rhinitis also serves as a major asthma trigger. In addition, C.V. should also ideally receive an intranasal corticosteroid if antihistamines (preferably nonsedating) do not provide optimal relief of her allergic rhinitis. Intranasal corticosteroid therapy not only offers excellent relief of nasal symptoms but also improves asthma control.[1] Good control of rhinitis is helpful in maintaining optimal asthma control[1] (see Chapter 20, Acute and Chronic Rhinitis).

Despite precautions listed in manufacturer literature that older (sedating) antihistamines should be avoided in asthma, these agents are safe in patients with asthma.[1] Nevertheless, nonsedating antihistamines are preferred.

Corticosteroids

CASE 18-5

QUESTION 1: S.T., a 12-year-old girl with severe-persistent asthma, has not been well controlled on mometasone 220 mcg (Asmanex) one inhalation daily (she admits to using it only when she feels as if she needs it) and uses as-needed inhaled albuterol MDI 5 or 6 times every day. When her symptoms worsen, she uses her "breathing machine" (nebulizer) at home. S.T. awakens most nights with wheezing. She has been hospitalized 4 times in the last 2 years and has required "bursts" of prednisone with increasing frequency. S.T. has missed many days of school in the past year and has withdrawn from physical education classes and her extracurricular sports activity after school. Her parents are concerned about her increased use of prednisone now that she is approaching puberty. S.T. is just finishing a 2-week course of prednisone 20 mg/day and has a round facies appearance typical of chronic oral corticosteroid use. On physical examination, S.T. has diffuse expiratory wheezes, and pulmonary function testing reveals significant reversibility. Her FEV_1 is only 60% predicted before use of albuterol in the physician's office and improves to 75% predicted 15 minutes after use of the SABA. What actions are needed to improve S.T.'s care?

Because S.T. is suffering needlessly and requiring frequent systemic corticosteroids, all efforts must be made to optimize other therapies and to minimize systemic corticosteroid toxicities. Although S.T. is receiving an ICS, she admits to poor adherence. Therefore, with her severe-persistent asthma, she initially needs higher-dose ICS therapy. Per EPR-3,[1] she should also receive a LABA. Although short bursts of prednisone (e.g., 40 mg/day for 3 days) are very helpful occasionally, frequent short courses often indicate the need to optimize other therapies. Some patients require courses of 1 to 2 weeks. S.T. is requiring longer frequent bursts and is showing signs of adverse effects. Obviously, S.T. and her parents also need a concerted and persistent effort in patient education as a partnership (refer to Patient Education and Outcomes sections).

ICS are chemically modified to maximize topical effectiveness while minimizing systemic toxicities. EPR-3[1] compares the dosages of ICS products. These differences in dosages (low, medium, and high) reflect differences among ICS in receptor-binding affinity and topical potency. There are also differences among these agents in oral bioavailability (i.e., absorption of drug that is swallowed after inhalation) and systemic availability via absorption from the lungs. Of these two variables, absorption from the lungs is the most likely contributor to possible hypothalamic–pituitary–adrenal (HPA) suppression or other systemic effects. Fortunately, the total absorption has not been shown to be clinically important except at the higher recommended dosages. Although the various ICS are not equipotent on a microgram-per-microgram basis, major differences in efficacy or adverse effects are not firmly established.[1] For patients with severe-persistent asthma, a logical choice would be a high-potency agent that would allow for a minimum number of inhalations per day, potentially improving treatment adherence. Furthermore, the delivery system used affects pulmonary deposition, but each available delivery system has established efficacy if used correctly.[1,69,70] The differences among the various dry powder inhalers are discussed later in this chapter. Addition of a spacer device to an MDI also enhances pulmonary deposition. In very high dosages (the equivalent of 1,600 mcg/day of beclomethasone dipropionate), all ICS produce some degree of HPA-axis suppression.[1] The clinical significance of this suppression has yet to be firmly established.

Although low-to-moderate dosages of ICS are accepted as being quite safe, very high dosages continue to be scrutinized regarding the potential adverse effects.[1] Clearly, for patients who require high dosages for optimal control of asthma, the benefits of therapy with these agents far outweigh the risks.[1] A possible association between prolonged, very high dosages of ICS and cataracts[71,72] and glaucoma[73] has been reported. EPR-3 has summarized research that has allayed concerns regarding use of ICS therapy and growth suppression in children (i.e., the decrease in growth velocity is small and not progressive, and appears to be quite minimal).[1,65,74]

CASE 18-5, QUESTION 2: How should S.T. be managed?

In the treatment of S.T., most clinicians would begin with a short course (e.g., 1 week) of systemic corticosteroids to maximally improve her pulmonary function. This approach is consistent with EPR-3,[1] which recommends gaining quick control. Using short-course systemic therapy is logical because it is inexpensive, efficacious, and associated with low risk. While gaining quick control with a short course of oral corticosteroids, it is logical to start ICS in many patients at a low[1,75]-to-moderate dosage. The evidence that ICS are highly effective in persistent asthma is unequivocal. Patients in this category who consistently take ICS are at a lower risk of hospitalization and death, and one study found an increased risk of death after discontinuation of ICS compared with patients who remained on these drugs.[76] ICS therapy should be initiated concomitantly with a short course of systemic corticosteroid therapy. Patient education at this time may have greater effectiveness because some patients are more attentive after having just experienced an exacerbation, and they know that change is needed to improve their health. Similar to adults, intensification of therapy with increasing the ICS dose, adding montelukast, or adding a LABA was found to be successful in pediatric patients, with the LABA being the most likely addition to be beneficial.[1,77–79] Because S.T.'s asthma is classified as severe persistent, it is reasonable to start her on a moderate-to-high dosage of an ICS in combination with a LABA (Fig. 18-8, Table 18-3). More aggressive therapy initially is especially important in S.T. because of her four hospitalizations in the last 2 years. In partnership with S.T. and her parents, her preference should be determined as to the delivery method (i.e., discuss options with her regarding breath-activated devices or MDI and spacer, including which spacer). Ideally, the clinician should recognize her emerging independence as a 12-year-old and talk with her alone and then with her parents. After S.T. is stabilized for 3 months, attempts should be made to slowly decrease the ICS dosage every 3 months until the lowest effective dosage is achieved. Administration of the total daily ICS dose is preferred twice daily or, in many patients with mild-persistent to moderate-persistent asthma, once daily.[1] Because adherence is a major determinant of success or failure with ICS and other therapies, simplified regimens and continued patient education and contact are essential.[1]

COMBINATION OF INHALED CORTICOSTEROIDS AND LONG-ACTING INHALED γ_2-AGONISTS

CASE 18-5, QUESTION 3: Because S.T. is 12 years old, what options are appropriate to minimize the ICS dosage, realizing that aggressive therapy is needed? What are the risks associated with LABAs? Clinicians should monitor for which local side effects in S.T. with ICS therapy?

LABAs have been very successful in prevention of “stepping up” the dose of ICS while markedly enhancing overall asthma control,[77–79] and this fact is reflected in EPR-3.[1] A reasonable therapeutic option for S.T. would be the combination of fluticasone 250 mcg and salmeterol 50 mcg via Diskus (Advair 250/50) 1 inhalation BID, the budesonide/formoterol (Symbicort) combination inhaler (160/4.5 mcg; 2 inhalations BID), the mometasone/formoterol (Dulera) combination inhaler (100/5 mcg; 2 inhalations BID), or the fluticasone furoate/vilanterol (Breo Ellipta) combination inhaler (200/25 mcg; 1 inhalation once daily). S.T. should be re-evaluated in 2 weeks. The plan is to step down the dose of fluticasone after excellent asthma control is achieved.

Adverse Effects Associated with Long-Acting Inhaled γ^2-Agonists

CASE 18-5, QUESTION 4: S.T.’s parents recently discovered an article in a national newspaper that addressed concerns of using LABAs because of an increased risk of death. Because S.T.’s parents have called and left a message for the clinician, what would be important information to share with her family regarding this issue? What other side effects should S.T. and her family be aware of?

Several randomized trials for more than a decade have demonstrated that LABAs have minimal adverse effects (e.g., tachycardia, tremor).[1,69,70,77–79] Although there are limited data, based primarily on one study (SMART),[80] there may be a very small increased risk of asthma-related death and asthma exacerbation in patients receiving LABAs. This small risk is likely attributable to patients receiving LABAs without concomitant ICS. In fact, EPR-3[1] recommends against the use of LABAs as monotherapy for long-term control of persistent asthma. SMART[80] data suggested that black patients may be at greater risk, but much more study is needed to confirm these data. LABA therapy should only be used in combination with ICS in patients with asthma. Both national[1] and international[81] asthma guidelines clearly state that combination ICS/LABA therapy for asthma is safe and effective. EPR-3[1] suggests giving equal consideration to a moderate dose of ICS alone or low-dose ICS combined with LABA for patients with moderate-persistent asthma. In 2010, the US Food and Drug Administration (FDA) offered recommendations regarding the use of LABA in patients with asthma, including always using combination products (ICS/LABA) versus two single-agent products to help ensure LABA are never used alone in asthma patients.[82] In response to the FDA, editorials by EPR-3 members and others question some aspects of the FDA recommendations.[83,84] For S.T., who has severe-persistent asthma, ICS/LABA combination therapy is preferred.[1]

Step-Down Treatment

CASE 18-5, QUESTION 5: After being adherent to her new therapy (fluticasone 250 mcg/salmeterol 50 mcg BID) for 1 month, S.T.'s asthma control has markedly improved. She required no ED visits or hospitalizations, was sleeping through the night, and began to exercise again. Her personal best PEF was 320 L/minute, and she was staying in her green zone (260–320 L/minute), requiring PRN albuterol no more than once per week. After 2 more months, S.T. continues to do well. Although S.T. clearly needs long-term ICS therapy, after 3 months of excellent response, her clinician is now ready to step down from high-dose fluticasone. What is a prudent approach to dosage reduction?

EPR-3[1] suggests stepping down the dose at a rate of 25% to 50% every 3 months to the lowest dose that maintains control. A step down to fluticasone 100 mcg/salmeterol 50 mcg (Advair 100/50) BID would be a reasonable reduction in therapy for S.T. If a single ICS product had been started in S.T. initially (e.g., budesonide, beclomethasone, fluticasone), the dosage reduction would normally proceed at a slower pace. However, fluticasone 100 mcg BID, especially in combination with salmeterol, will likely be an adequate dose for S.T. After S.T.'s dose of fluticasone was stepped down to 200 mcg/day, she started requiring only slightly more PRN albuterol (but still was symptom free most days). Another consideration for S.T. is that recent international evidence-based guidelines (Global Initiative for Asthma—GINA[81]) suggest an alternative approach for patients at risk of severe exacerbations. Patients receiving low-dose ICS combined with formoterol may be instructed to not only use their routine twice-daily scheduled doses, but also use the same combination for "as-needed" doses for quick relief instead of PRN albuterol.[81] Although this approach is not commonly used in the USA, it is an option per GINA.[81]

CASE 18-5, QUESTION 6: If symptoms recur during step-down, what management could possibly facilitate dosage reduction of the ICS in S.T.?

During follow-up evaluations, clinicians should carefully investigate factors that may contribute to poor asthma control, including exposure to inhalant allergens, indoor or outdoor irritants, medications, and tobacco smoke. Secondhand smoke exposure has been demonstrated to reduce the benefit of ICS in children and necessitate step-up therapy, and asthma patients who smoke have reduced response to ICS therapy.[85,86]

Leukotriene Modifiers

CASE 18-6

QUESTION 1: P.W. is a 52-year-old man with mild-persistent asthma. His asthma symptoms began when he was 2 years of age, and he has never smoked. P.W. has had numerous drug regimens for his asthma during the years, but he tells his physician that he wants the simplest regimen possible and that he prefers oral medication if at all possible. What is a good choice for controller therapy in P.W.?

In patients of any age with mild-persistent asthma, and certainly in children or adolescents, an oral agent such as montelukast with once-daily dosing at bedtime (or zafirlukast with twice-daily dosing) has obvious advantages. Zileuton is another leukotriene modifier, but it has more drug interactions and adverse effects than the other available agents. An ICS is the preferred treatment for mild-persistent asthma. Studies comparing ICS with leukotriene receptor agonists have consistently demonstrated the superiority of ICS for most asthma outcome measures,[1] but in patients (adults or children) who much prefer oral therapy to inhaling medication every day, leukotriene modifiers are a reasonable option. The simplest and safest possible oral controller regimen for P.W. is montelukast 10 mg at bedtime (with PRN inhaled albuterol). Bedtime dosing with montelukast is recommended because it will have peak activity late at night and in the early morning hours, when asthma symptoms tend to be more frequent. However, montelukast may be taken at any time of day as long as it is taken at a consistent time that is convenient for the patient. It is likely that this regimen will result in very good asthma control. If P.W. does not have good control of his asthma when he returns to the clinic in a few weeks, switching to a low-dose ICS in the evening only would keep the regimen simple while enhancing efficacy.

Theophylline

DOSING

CASE 18-7

QUESTION 1: K.J., a 14-year-old, 40-kg girl, has a history of recurring cough and wheezing. These symptoms worsen on vigorous running or when she has an upper respiratory infection. She has not required hospitalization for these symptoms but has missed a few school days. She has symptoms daily and uses her albuterol inhaler more than 2 times daily. K.J. has a family history of asthma. A diagnosis of moderate-persistent asthma is made. How should K.J. be managed?

Because K.J. has moderate-persistent asthma, treatment with an anti-inflammatory agent is indicated. A medium-dose ICS or a low-dose ICS plus a LABA is the preferred treatment in a 14-year-old child with moderate-persistent asthma.[1] However, not all healthcare professionals follow the latest evidence-based guidelines, and K.J.'s clinician opts to prescribe theophylline in combination with a low dose of budesonide via the Flexhaler.

CASE 18-7, QUESTION 2: What dosage of theophylline is appropriate for K.J.?

Low doses of budesonide combined with twice-daily theophylline that resulted in a median serum theophylline concentration of 8.7 mcg/mL were superior in efficacy to high-dose budesonide as single controller therapy.[87] Thus, it is wise to give a therapeutic trial with low-dose theophylline initially, aiming for serum concentrations between 5 and 10 mcg/mL. In the nonacute asthma patient in whom the theophylline dose requirement is unknown, dosages suggested for ages older than 1 year of age are listed in Table 18-5 and infant dosing is listed in Table 18-6. Accordingly, the initial dosage in K.J. would be 300 mg/day in divided doses (i.e., 150 mg every 12 hours). If tolerated, the dosage is increased at 3-day intervals by about 25% to the mean dose that usually is needed to produce a peak theophylline serum concentration between 5 and 10 mcg/mL. The final dosage can be adjusted by serum concentration monitoring. Serum theophylline concentrations should be obtained at steady state (i.e., when there have been no missed doses and no extra doses have been taken for at least 48 hours).

TOXICITY

CASE 18-7, QUESTION 3: K.J. now complains of headache and difficulty in getting to sleep. Why should a theophylline serum concentration be evaluated?

Theophylline side effects can be related to excessive serum concentrations, or adverse effects can be transient and unrelated to the amount in serum. Unfortunately, it is not always possible to determine which it might be. Side effects can include headache, nausea, vomiting, irritability or hyperactivity, insomnia, and diarrhea. With higher serum theophylline levels, cardiac arrhythmias, seizures, and death can occur.[88] Less severe symptoms may not be present before the onset of cardiac arrhythmias or seizures and cannot be relied on as a forewarning of these more serious adverse theophylline effects. It is important not to ignore any symptom consistent with theophylline toxicity. The insomnia and headaches experienced by K.J. may not be associated with excessive (i.e., out of the usual therapeutic range) serum theophylline concentrations, but a reduction in dosage should be contemplated because some patients experience toxicity when serum theophylline concentrations are within the therapeutic range. Guidelines for managing toxicity have been revised.[88]

Table 18-5

Theophylline Dosing Guide for Chronic Use

Starting dose for children 1–15 years <45 kg: 12–14 mg/kg/day to maximum of 300 mg/day[a,b]
Starting dose for adults and children 1–15 years >45 kg: 300 mg/day
Titrate dose upward after 3 days if necessary and if tolerated to:
▪ 16 mg/kg/day to maximum of 400 mg/day in children 1–15 years <45 kg ▪ 400 mg/day in adults and children >45 kg
Titrate dose upward after 3 more days if necessary and if tolerated to:
▪ 20 mg/kg/day to a maximum of 600 mg/day in children 1–15 years <45 kg ▪ 600 mg/day in adults and in children >45 kg

[a] Dose using ideal body weight or actual body weight, whichever is less. These dosages do not apply if liver disease, heart failure, or other factors documented to affect theophylline clearance are present. Doses must be guided by monitoring serum concentrations to ensure optimal safety and efficacy.

[b] Dosing schedule dependent on product selected; sustained-release products are much preferred, if at all possible.

Table 18-6

Food and Drug Administration Guidelines for Theophylline Dosing in Infants

Premature Neonates[a]
<24 days postnatal age: 1.0 mg/kg every 12 hours ≥24 days postnatal age: 1.5 mg/kg every 12 hours
Term Infants and Infants Up to 52 Weeks of Age
Total daily dose (mg) = ([0.2 × age in weeks] + 5.0) × (kg body weight) ▪ Up to age 26 weeks; divide dose into 3 equal amounts administered at 8-hour intervals ▪ >26 weeks of age; divide dose into 4 equal amounts administered at 6-hour intervals

[a] Final doses adjusted to a peak steady-state serum theophylline concentration of 5–10 mcg/mL in neonates and 10–15 mcg/mL in older infants.

Source: Hendeles L et al. Revised FDA labeling guideline for theophylline oral dosage forms. Pharmacotherapy. 1995;15:409.

DRUG INTERACTIONS

CASE 18-8

QUESTION 1: T.R., a 55-year-old woman with asthma, is well controlled on theophylline SR 300 mg BID, albuterol two puffs QID PRN, and mometasone 220 mcg (Asmanex) one inhalation at bedtime. A peak theophylline serum concentration obtained 3 months ago was 14 mcg/mL. Six months ago, on the same dose of theophylline, her serum concentration was 15 mcg/mL. T.R. presents with an upper respiratory tract infection, and clarithromycin 500 mg BID is prescribed. Is this antibiotic appropriate?

A large number of medications inhibit cytochrome P-450 (CYP) isoenzymes and are capable of inhibiting the metabolism of theophylline. Because theophylline is metabolized by CYP 1A2, 3A3, and 2E1, inhibitors of these isoenzymes can cause clinically significant interactions.[56,88] Cimetidine, clarithromycin, and some (but not all) of the quinolone antibiotics (e.g., ciprofloxacin) are well documented to inhibit theophylline metabolism.[1,56] Because numerous other drugs inhibit the metabolism of theophylline, all patients receiving this agent should be screened carefully for potential interactions. As with any drug interaction, the mechanism, time course, management, and clinical significance should be assessed before any interventions. For example, cimetidine decreases theophylline clearance within 24 hours, and this interaction should be circumvented by using another histamine H_2-blocker or a proton-pump inhibitor (Table 18-7). Classic inducers (e.g., rifampin) of cytochrome P-450 also affect theophylline clearance, and patients should be monitored for decreased serum concentrations. In T.R., the interaction with clarithromycin can easily be circumvented by using azithromycin, which does not affect theophylline metabolism.

Table 18-7

Factors Affecting Serum Theophylline Concentrations

Factor[a]	Decreases Theophylline Concentrations	Increases Theophylline Concentrations	Recommended Action
Food	↓ or delays absorption of some sustained-release theophylline (SR) products	↑ rate of absorption (fatty foods)	Select theophylline preparation that is not affected by food.
Diet	↑ metabolism (high protein)	↓ metabolism (high carbohydrate)	Inform patients that major changes in diet are not recommended while taking theophylline.
Systemic, febrile viral illness (e.g., influenza)		↓ metabolism	Decrease theophylline dose according to serum concentration level.

			Decrease dose by 50% if serum concentration measurement is not available.
Hypoxia, cor pulmonale, and decompensated congestive heart failure, cirrhosis		↓ metabolism	Decrease dose according to serum concentration level.
Age	↑ metabolism (1–9 years)	↓ metabolism (<6 months, elderly)	Adjust dose according to serum concentration level.
Phenobarbital, phenytoin, carbamazepine	↑ metabolism		Increase dose according to serum concentration level.
Cimetidine		↓ metabolism	Use alternative histamine H_2-antagonist (e.g., famotidine or ranitidine).
Macrolides: TAO, erythromycin, clarithromycin		↓ metabolism	Use alternative antibiotic or adjust theophylline dose.
Quinolones: ciprofloxacin, enoxacin, pefloxacin		↓ metabolism	Use alternative antibiotic or adjust theophylline dose.
Rifampin	↑ metabolism		Increase dose according to serum concentration level.
Ticlopidine		↓ metabolism	Decrease dose according to serum concentration level.
Smoking	↑ metabolism		Advise patient to stop smoking; increase dose according to serum concentration level.

[a] This list is not all inclusive; for discussion of other factors, see package inserts.

TAO, troleandomycin.

Modified from National Institutes of Health. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. Bethesda, MD: National Heart, Lung, and Blood Institute; 2007. NIH publication 07-4051.

Anticholinergics

CASE 18-9

QUESTION 1: R.K. is a 24-year-old African American graduate medical student with moderate-persistent asthma, which has been well controlled for 10 years with ICS therapy (beclomethasone HFA 80 mcg twice daily) and albuterol PRN. Recently, he has noticed that his asthma symptoms have worsened and he is requiring his albuterol inhaler 3 or 4 times per week, which causes him to have a resting tremor and feel anxious. One of his colleagues suggests that he should inquire about an anticholinergic medication in addition to his ICS. Is this appropriate?

Until now, anticholinergic agents have had limited use in asthma except in the

ED[1,89] and a few other rare situations.[90] However, in a recent study of tiotropium, a long-acting once-daily anticholinergic agent, in persistent asthmatic patients poorly controlled on ICS alone, researchers demonstrated that the addition of tiotropium to ICS therapy was not inferior to the effects of adding salmeterol to ICS therapy and was superior to doubling the inhaled steroid dose.[91] The morning PEF and evening PEF were significantly higher in patients receiving tiotropium than those receiving a doubling of the ICS dose. A subsequent randomized, controlled trial found that tiotropium therapy added to combination ICS/LABA in suboptimally controlled adult asthma patients was superior to placebo.[92]

Although tiotropium is not identified in EPR-3 as an option for persistent asthma patients, a therapeutic trial in R.K. may be considered given these new data, especially given his anxiousness and tremor with the increased albuterol use. A similar response to LABAs may be seen. In 2015, Spiriva Respimat was approved for use as maintenance therapy in patients with asthma, ages >12-year-old, who remain symptomatic despite already receiving combination ICS/LABA treatment.

Anti-Immunoglobulin E Therapy

CASE 18-10

QUESTION 1: M.M. is a 30-year-old woman with severe-persistent asthma. Despite optimal assessment, drug therapy, environmental control, and patient education per the principles of management detailed in EPR-3, she has had two recent hospitalizations as a result of asthma. Her allergist is considering anti-IgE therapy. Is M.M. a good candidate for such therapy? How would it be given? M.M. has a pretreatment IgE level of 90 international units/mL, and she weighs 55 kg.

Omalizumab (Xolair) is a humanized monoclonal anti-IgE antibody that binds to free IgE in serum. Thus, binding of IgE to high-affinity receptors on mast cells is subsequently inhibited, and the initiation of the allergic inflammatory cascade is blocked.[1,93–96] Omalizumab is effective in reducing oral and ICS dose requirements in patients with severe asthma and in reducing exacerbations.[93–96] This novel therapy is administered as a 150- to 375-mg subcutaneous injection every 2 or 4 weeks. The dose and frequency of administration are based on the serum total IgE level (international units/mL) and the patient's body weight. Therefore, M.M.'s omalizumab dose is 150 mg subcutaneously every 4 weeks.

Common side effects associated with omalizumab include injection site reactions, upper respiratory tract infections, sinusitis, and headache. Less common but potentially serious adverse effects include anaphylaxis (0.2% in postmarketing spontaneous reports), which can occur after any dose even if previous doses have been well tolerated and 24 or more hours after administration, and the development of malignant neoplasms (0.5% of omalizumab-treated patients compared with 0.2% in control patients).

Because omalizumab is expensive and must be administered as a subcutaneous injection, it should be reserved for patients with severe asthma who are not adequately controlled with standard therapies. Despite the high cost, anti-IgE therapy might be cost effective in selected patients with severe disease (e.g., those with frequent ED visits and hospitalizations) because an estimated less than 5% of asthma patients (severe disease) account for greater than 50% of the dollars spent for asthma care.[97]

CASE 18-10, QUESTION 2: Because the nurse prepares the dose of omalizumab for M.M., what are some special considerations regarding administering and monitoring this drug?

After reconstitution of omalizumab, the drug must be administered within 4 hours if stored at room temperature and within 8 hours when refrigerated. As a result of its viscosity, the injection may take 5 to 10 seconds. No more than 150 mg is injected at each site. Although the risk of anaphylaxis is rare (0.2%),[98] patients should stay in the physician's office for at least 30 minutes after injection of omalizumab and be educated regarding the signs and symptoms of anaphylaxis. After leaving the physician's office, patients should seek emergency medical treatment at the first sign of anaphylaxis. Despite the low risk of severe allergic reactions, in 2010 the manufacturer added a black box warning about the risk of anaphylaxis.[98]

EXERCISE-INDUCED ASTHMA

CASE 18-11

QUESTION 1: T.W., a 33-year-old woman, presents to the clinic with a history of severe coughing and chest tightness after exercise. She recently joined an exercise club to lose weight but is unable to keep up with others of her own age and relative condition when jogging outside. She recalls having mild respiratory problems as a young child but has never taken any asthma medications. She has a positive treadmill test for exercise-induced asthma (EIA). How should T.W. be treated?

During sustained exercise, at least 90% of patients with asthma experience an initial improvement in pulmonary functions quickly followed by a significant decline (Fig. 18-11). This phenomenon may be the only symptom of subclinical asthma.[1,99] Patients can be diagnosed by measuring the FEV_1 or PEF before and after exercise (6- to 8-minute treadmill or bicycle exercise test). A reduction of FEV_1 by more than 15% of the baseline value is a positive test.

Hyperventilation of cold, dry air increases the sensitivity to EIA and induces bronchospasm.[99] The main stimulus for EIA is respiratory heat loss, water loss, or both,[99] while breathing heated, humidified air completely blocks EIA in many patients.[99] Masks are indicated for patients with EIA in the wintertime, and patients with severe asthma accompanied by EIA also should be encouraged to swim or engage in other indoor exercise that does not promote EIA. A warm-up period before strenuous exercise is helpful in some patients. With appropriate premedication, most EIA can be prevented, so virtually all patients with stable asthma should be encouraged to exercise. The mechanism of bronchoconstriction after airway heat and water loss is still incompletely understood.[99]

Although several drugs inhibit EIA, SABAs are generally the agents of choice for prophylaxis.[1,99] For typical periods of exercise (e.g., <3 hours), pretreatment with agents such as albuterol 5 to 15 minutes before exercise usually provides excellent protection from EIA.

For prolonged periods of exercise, LABAs (formoterol, salmeterol) provide several hours of protection.[1,100] Two differences in formoterol and salmeterol include the delivery systems for inhalation and the onset of action. If either of these agents is to be used to prevent EIA, it is important for the patient to inhale the medication at the proper time before exercise. Formoterol should be inhaled at least 15 minutes before exercise, and salmeterol administration should occur at least 30 minutes before vigorous activity. Patients who are receiving therapy every 12 hours with either drug concomitantly with ICS for long-term control of asthma should already be protected and therefore only use albuterol if symptoms occur after exercise. With maintenance therapy, as opposed to single doses before exercise, bronchoprotection from exercise may be reduced to 5 hours with LABAs.[1] Leukotriene receptor antagonists (e.g., montelukast once-daily chronic therapy) have also been demonstrated to prevent EIA.[101] Finally, it is important to point out that in persistent asthma, long-term anti-inflammatory therapy is helpful in reducing the response to most asthma triggers, including exercise.[1] For most patients who have EIA only, use of a SABA 15 minutes before exercise is the only therapy needed.

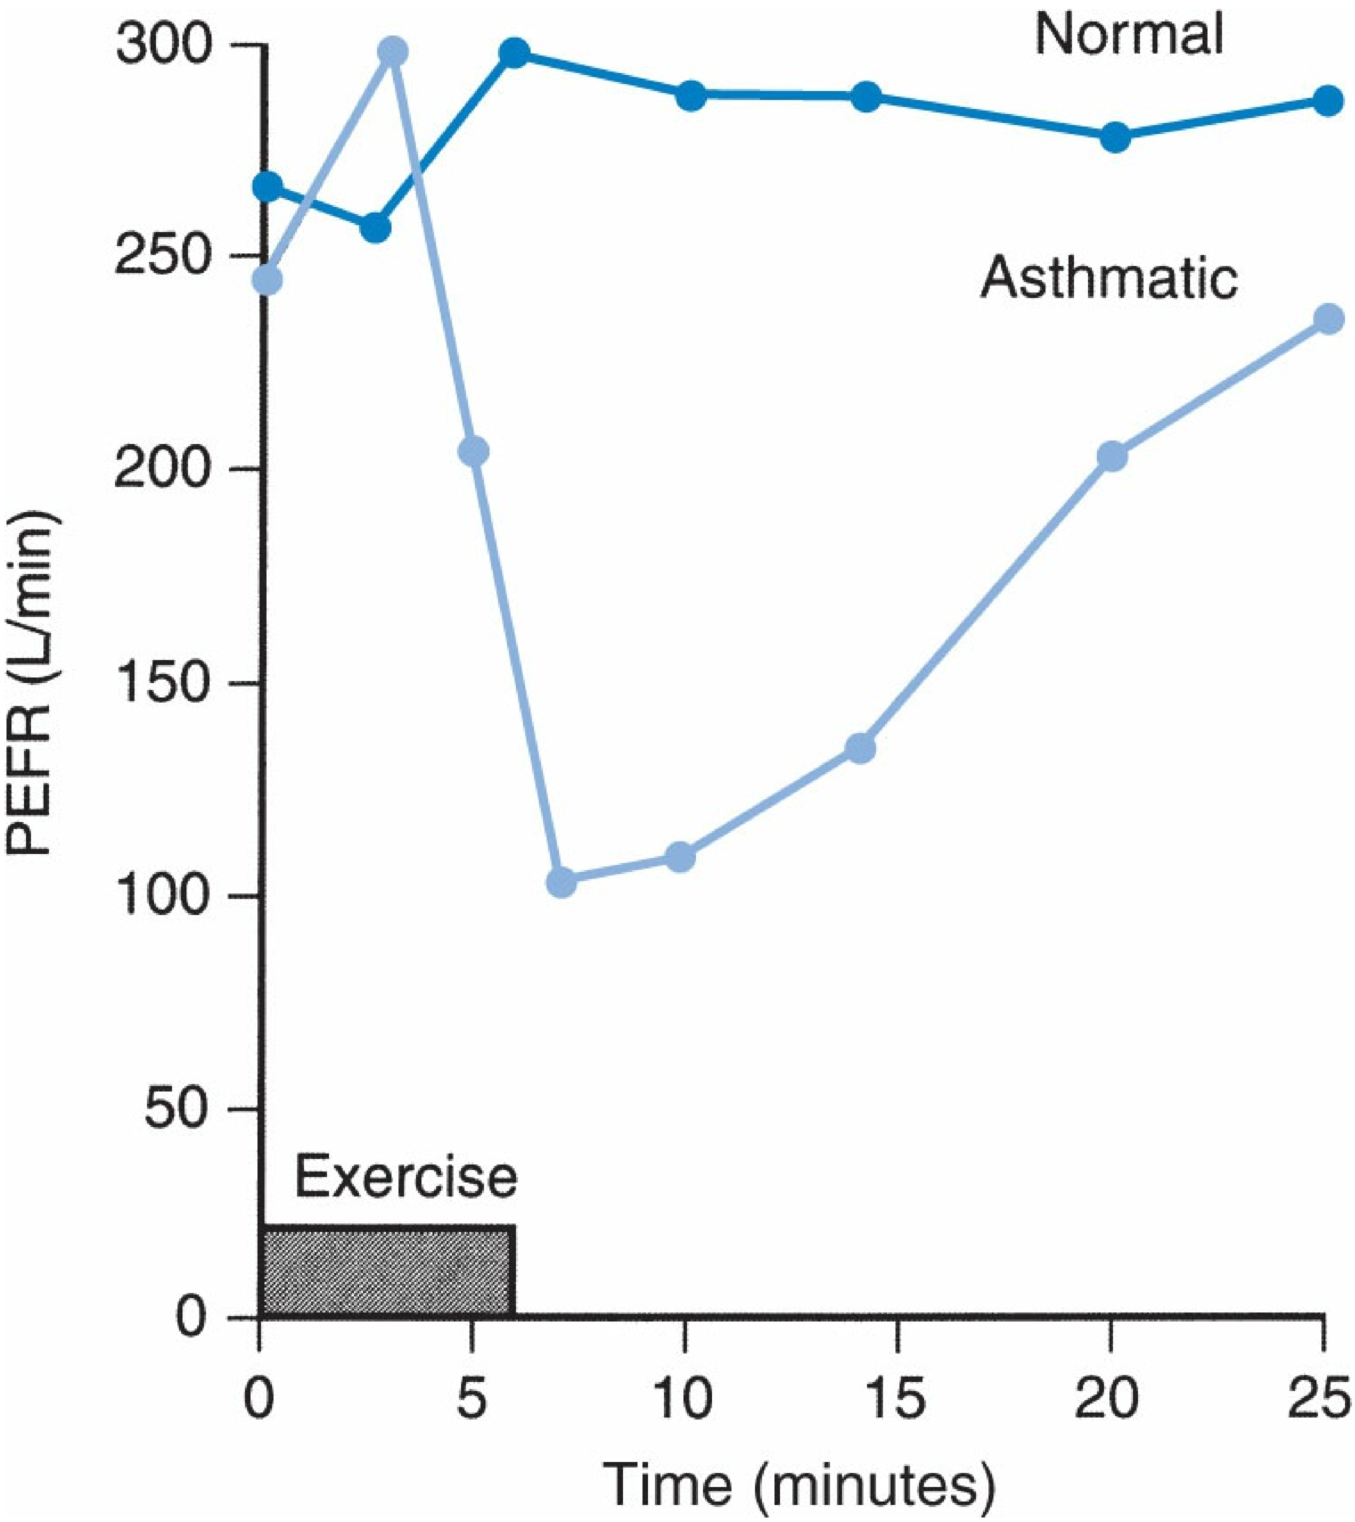

Figure 18-11 Changes in peak expiratory flow rate with exercise in an asthmatic and normal subject. PEFR, peak expiratory flow rate.

Because of the hyperventilation of relatively cool, dry air, jogging is a potent stimulus for EIA. A number of possible therapeutic interventions exist for T.W. She could be encouraged to swim because the inhalation of humidified warm air is less likely to produce EIA. However, if she wishes to continue jogging, two inhalations of a SABA (e.g., albuterol) from a metered-dose aerosol 15 minutes before exercise should provide adequate protection for 2 to 3 hours. If outdoor temperatures are quite cool or cold, T.W. should jog indoors. T.W. also should be counseled to take two additional inhalations if she "breaks through" the initial protection and experiences tightness.

CASE 18-12

QUESTION 1: W.L., a 17-year-old boy, presents to the clinic with a complaint of dyspnea and coughing that has limited his ability to keep up with his basketball teammates. He states that it is worse when playing outdoors unless the gym is cold and that it seems to be worse (occurring sooner during exercise) than a month ago. W.L. experienced several bouts of bronchitis as a young child but has not had any problems for the past 6 years. His symptoms are consistent with EIA. How should his EIA be treated?

W.L. presents a special problem in that he is a teenager. Both for adolescents and children, peer pressure usually is extremely significant. Optimal prophylaxis is important to allow W.L. to compete at his best level. Embarrassment about not keeping up with teammates can be very hurtful now, and it has implications for setting habits of exercise into adulthood. Many adults with asthma do not exercise because they think they cannot do so based on childhood experiences. Lack of exercise can have a negative impact on physiologic and psychologic well-being. W.L. should receive preventive treatment with an inhaled β_2-agonist. The question is whether he should receive a short-acting or a long-acting agent. The clinician should probe as to the duration of exercise. If W.L. exercises for longer than 3 hours, formoterol or salmeterol administered 15 to 30 minutes before exercise would be a logical choice. Finally, the clinician should verify that exercise is the only factor that precipitates asthma symptoms. It could be that further questioning of W.L. will reveal persistent asthma or mild intermittent asthma beyond EIA only. If that is the case, long-term ICS or montelukast therapy should be started to reduce overall airway hyperresponsiveness.

PATIENT EDUCATION

CASE 18-13

QUESTION 1: A.B., a 26-year-old woman, calls her clinician and states that she has run out of her albuterol MDI. She has a prescription for a budesonide dry powder inhaler but admits that she does not use this medication "because it doesn't seem to work as well as her albuterol MDI." A.B. has had asthma all of her life. She complains of symptoms most days but has not required visits to the ED or hospitalizations. The provider determines that A.B. is bothered most about daily shortness of breath and worries that her condition may get worse. What should the provider do in this situation?

Table 18-8

Key Educational Messages: Teach and Reinforce at Every Opportunity

Basic Facts About Asthma

- The contrast between airways of a person who has and a person who does not have asthma; the role of inflammation
- What happens to the airways in an asthma attack

Roles of Medications—Understanding the Difference Between the Following:

- Long-term control medications: prevent symptoms, often by reducing inflammation. Must be taken daily. Do no expect them to give quick relief.
- Quick-relief medications: Short-acting β_2-agonists relax muscles around the airway and provide prompt relief o symptoms. Do not expect them to provide long-term asthma control. Using quick-relief medication on a daily basis indicates the need for starting or increasing long-term control medications.

Patient Skills

- Taking medications correctly. Inhaler technique (demonstrate to patient and have the patient return the demonstration). Use of devices, such as prescribed valved holding chamber, spacer, nebulizer.
- Identifying and avoiding environmental exposures that worsen the patient’s asthma (e.g., allergens, irritants, tobacco smoke).
- Self-monitoring to:
  - Assess level of asthma control
  - Monitor symptoms and, if prescribed, peak flow
  - Recognize early signs and symptoms of worsening asthma.
- Using written asthma action plan to know when and how to:
  - Take daily actions to control asthma
  - Adjust medication in response to signs of worsening asthma
  - Seek medical care as appropriate.

Reprinted from National Institutes of Health. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. Bethesda, MD: National Heart, Lung, and Blood Institute; 2007. NIH publication 07-4051.

If optimal long-term drug therapy of asthma is prescribed, treatment may still fail or be suboptimal if the patient does not receive adequate education. Patients with asthma require special educational efforts because of the use of inhalation devices and peak flow meters. In addition, it often is a major challenge to have patients and parents understand the critical importance of long-term daily controller therapy and environmental control. Of course, an important first step in educating asthma patients is to be caring and a good listener. Rather than sharing your knowledge initially, it is important to help establish a “partnership” with the patient by first asking the following question: “What is bothering you the most about your asthma?” Really listening to the patient and then addressing patient concerns is extremely important to successful education and long-term management. EPR-3 lists several patient education activities in Table 18-8.[1]

Clinicians can be of invaluable assistance to the patient by repeatedly reinforcing education on the necessity of using anti-inflammatory (and combined ICS/LABA) therapies on a regular schedule. Many patients underuse long-term preventive therapy because no health professional took the time to adequately instruct them that most asthma symptoms are preventable. Although underusing the most important medicines for long-term control, many patients overuse “quick relievers” (i.e., SABAs). Healthcare providers must be able to detect these problems and intervene to enhance patient care.

Table 18-9

Steps to Correct Use of Metered-Dose Inhalers

1. Shake the inhaler well and remove the dust cap.
2. Exhale slowly through pursed lips.[a,b]
3. If using the “closed-mouth” technique, hold the inhaler upright and place the mouthpiece between your lips. Be careful not to block the opening with your tongue or teeth.
4. If using the “open-mouth” technique, open your mouth wide and hold the inhaler upright 1–2 inches from your mouth, making sure the inhaler is properly aimed.
5. Press down on the inhaler once as you start a slow, deep inhalation.
6. Continue to inhale slowly and deeply through your mouth. Try to inhale for at least 5 seconds.
7. Hold your breath for 10 seconds (use your fingers to count to 10 slowly). If 10 seconds makes you feel uncomfortable, try to hold your breath for at least 4 seconds.
8. Exhale slowly.[c]
9. Wait at least 30–60 seconds before inhaling the next puff of medicine.

[a] If using a spacer, see manufacturer’s instructions. Same basic principles of slow, deep inhalation with adequate breath-hold apply. With spacers, put mouthpiece on top of your tongue to ensure that tongue does not block aerosol.

[b] As long as exhalation is slow, exhale can take place for several seconds. Some experts insist on exhaling only a tidal volume, but the key is to exhale slowly.

[c] If patient has concomitant rhinitis, exhaling through the nose may be of benefit when using corticosteroids or ipratropium (i.e., some medication may deposit in nose).

Because a large percentage of patients have difficulty using MDIs, teaching patients the correct use of MDIs (alone or in combination with spacers) and dry powder inhalers is absolutely essential.[1,102,103] In one study, 89% of patients could not perform all of the steps for MDI use correctly.[104] Competent teaching requires observation of the patient using the devices initially and again on repeat visits to the clinic, hospital, or community pharmacy. Telling the patient about correct use is inadequate. Health professionals must demonstrate use of the devices (live or with videotapes) for patients who cannot use the devices correctly. For videos that show proper use of many types of asthma inhalers, go to **http://www.nationaljewish.org/healthinfo/multimedia/asthma-inhalers.aspx** for a video of how to use a nebulizer, go to **http://www.nationaljewish.org/healthinfo/medications/lung-diseases/devices/nebulizers/instructions.aspx**.

Although there is more than one correct way to use an MDI, Table 18-9 summarizes two commonly accepted approaches.[1,102] Many asthma experts prefer to use spacers to help ensure optimal efficacy. Spacers should be used in virtually all patients receiving ICS via an MDI, even those with perfect MDI technique, because spacers enhance efficacy and reduce the risk of oropharyngeal candidiasis.[105,106] On the other hand, spacers do not add efficacy to correct use of a β_2-agonist MDI.[107] Although any spacer can be helpful, marketed devices that are valved holding chambers and have a flow indicator whistle when inhalation is fast are preferred (e.g., AeroChamber).

Studies have shown that health professionals, like some patients, generally are not competent in using MDIs.[108] Obviously, the clinician should practice with a placebo inhaler and gain competence before teaching a patient. Among clinicians who educate patients, pharmacists can be helpful in teaching correct use of MDIs.[109] Unfortunately, one study showed that community pharmacists commonly are not providing such teaching.[110]

In addition to teaching the correct use of MDIs and spacers, clinicians should help patients via education regarding the correct use of breath-activated dry powder inhalers (e.g., Twisthaler, Diskus, Aerolizer, HandiHaler, Flexhaler) and nebulizing machines.[1] When using the Flexhaler, for example, patients must clearly understand the need for a rapid (preferably 60 L/minute), deep inhalation (not slow as with an MDI).[111] Such rapid PIF is achievable by some young children, but many children younger than 8 years of age have difficulty reaching PIF greater than 60 L/minute.[111] With the Diskus, PIF does not have to be as rapid as with Flexhaler, but it should be greater than 30 L/minute.[112] In addition, patients need to breath-hold 10 seconds if possible, as with an MDI.

Asthma Self-Management Plans

Objective monitoring of lung function at home with the use of peak flow meters can be very helpful to patients and healthcare professionals. EPR-3 discusses the debates about PEF versus symptom-based action plans.[1] Use of peak flow meters may be valuable in patients who have had severe exacerbations and those who are “poor perceivers” of deteriorating asthma control. Instructing patients on the correct use of the devices, including use of the green, yellow, and red zones, is essential.[1] After establishing that optimal therapy has maintained the PEF in the “green zone” in the early morning, most patients can simply verify their values once daily in the early morning. Analogous to a traffic light, green, yellow, and red zones have been established to guide the patient and clinician. The green zone refers to a PEF that is 80% to 100% of “personal best” and generally indicates that therapy is providing good control. Before a course of optimal therapy to attain a personal best, the zones are set based on predicted values found in each peak flow meter package insert. The yellow zone indicates a PEF that is 50% to 79% of personal best. Patients should be instructed to call their physician or other healthcare provider for adjustment in preventive medication if the PEF stays in the yellow zone after using two puffs of a β_2-agonist. The red zone indicates a PEF that is less than 50% of personal best. The patient should know to call his or her healthcare provider immediately if the use of an inhaled β_2-agonist does not bring the PEF to the yellow or green zone. Figure 18-12 provides an example of PEF monitoring, and Figure 18-13 gives an example of a written action plan.

Correct use of the peak flow meter includes standing, inhaling completely, forming a tight seal with the lips around the mouthpiece, exhaling as hard and fast as possible (blast!), and repeating this maneuver twice.

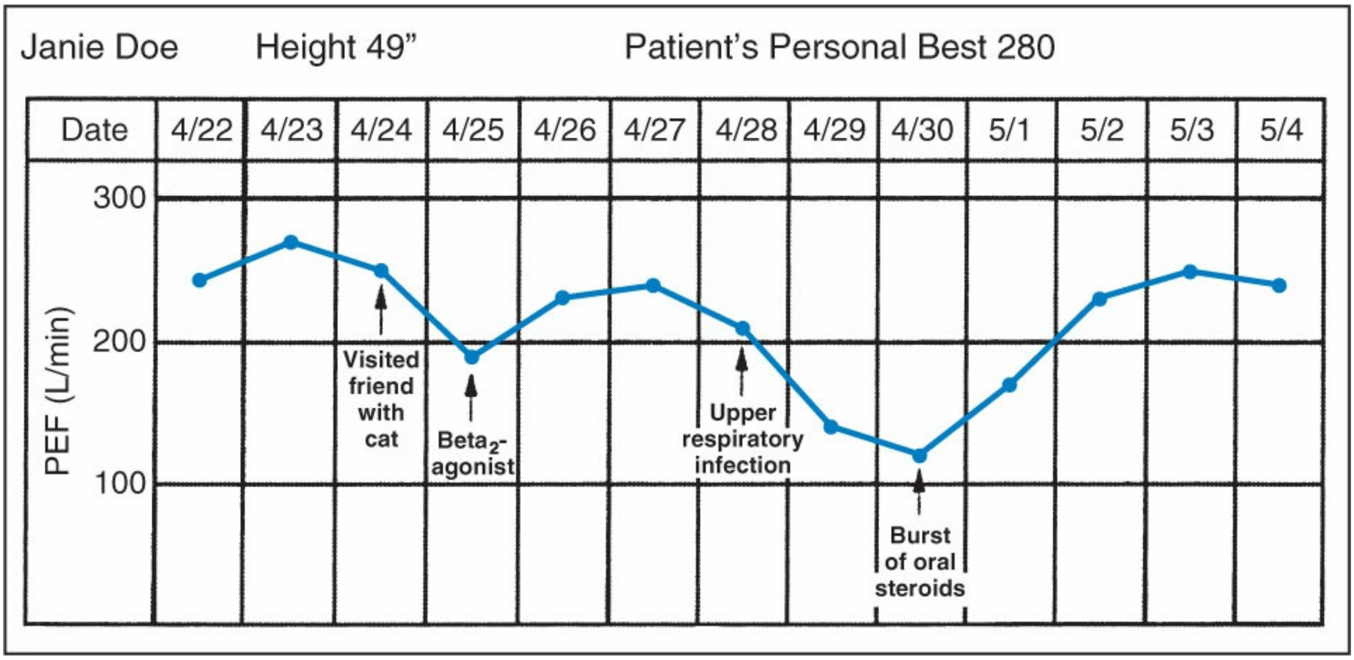

Figure 18-12 Asthma changes with time: patient monitoring and follow-up required. PEF, peak expiratory flow. (Adapted from National Institutes of Health. Practical Guide for the Diagnosis and Management of Asthma. Bethesda, MD: National Heart, Lung, and Blood Institute; 1997. NIH publication 97-4053.)

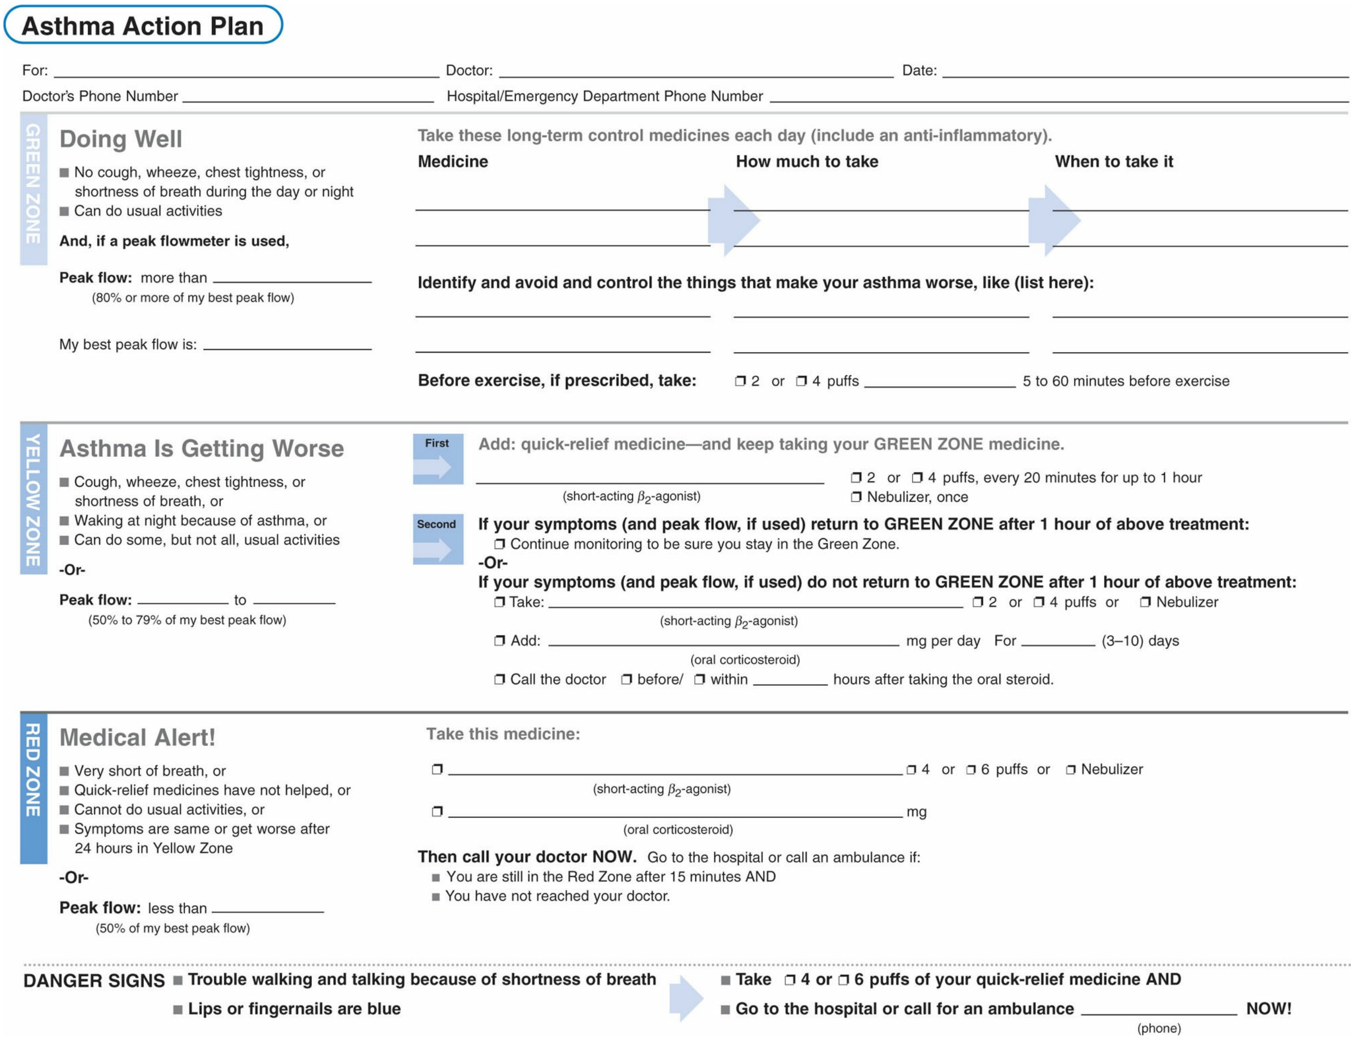

Asthma Action Plan

For: ________ Doctor: ________ Date: ________

Doctor's Phone Number ________ Hospital/Emergency Department Phone Number ________

GREEN ZONE

Doing Well

- No cough, wheeze, chest tightness, or shortness of breath during the day or night
- Can do usual activities

And, if a peak flowmeter is used,

Peak flow: more than ________
(80% or more of my best peak flow)

My best peak flow is: ________

Take these long-term control medicines each day (include an anti-inflammatory).

Medicine	How much to take	When to take it
________	________	________
________	________	________

Identify and avoid and control the things that make your asthma worse, like (list here):

________ ________ ________

________ ________ ________

Before exercise, if prescribed, take: ☐ 2 or ☐ 4 puffs ________ 5 to 60 minutes before exercise

YELLOW ZONE

Asthma Is Getting Worse

- Cough, wheeze, chest tightness, or shortness of breath, or
- Waking at night because of asthma, or
- Can do some, but not all, usual activities

-Or-

Peak flow: ________ to ________
(50% to 79% of my best peak flow)

First Add: quick-relief medicine—and keep taking your GREEN ZONE medicine.

________ ☐ 2 or ☐ 4 puffs, every 20 minutes for up to 1 hour
(short-acting β_2-agonist) ☐ Nebulizer, once

Second **If your symptoms (and peak flow, if used) return to GREEN ZONE after 1 hour of above treatment:**
☐ Continue monitoring to be sure you stay in the Green Zone.

-Or-

If your symptoms (and peak flow, if used) do not return to GREEN ZONE after 1 hour of above treatment:
☐ Take: ________ ☐ 2 or ☐ 4 puffs or ☐ Nebulizer
(short-acting β_2-agonist)
☐ Add: ________ mg per day For ________ (3–10) days
(oral corticosteroid)
☐ Call the doctor ☐ before/ ☐ within ________ hours after taking the oral steroid.

RED ZONE

Medical Alert!

- Very short of breath, or
- Quick-relief medicines have not helped, or
- Cannot do usual activities, or
- Symptoms are same or get worse after 24 hours in Yellow Zone

-Or-

Peak flow: less than ________
(50% of my best peak flow)

Take this medicine:

☐ ________ ☐ 4 or ☐ 6 puffs or ☐ Nebulizer
(short-acting β_2-agonist)
☐ ________ mg
(oral corticosteroid)

Then call your doctor NOW. Go to the hospital or call an ambulance if:
- You are still in the Red Zone after 15 minutes AND
- You have not reached your doctor.

DANGER SIGNS
- **Trouble walking and talking because of shortness of breath**
- **Lips or fingernails are blue**

- **Take ☐ 4 or ☐ 6 puffs of your quick-relief medicine AND**
- **Go to the hospital or call for an ambulance** ________ **NOW!**
(phone)

Figure 18-13 Sample asthma action plan. (Adapted from National Institutes of Health. Expert Panel Report 3. Guidelines for the Diagnosis and Management of Asthma. NIH Publication No. 08-4051.0; 2007.)

The best of three attempts should be recorded. Beyond giving maximal effort when using peak flow meters, patients should be instructed to place the instrument well into the mouth on top of the tongue to avoid acceleration of air in the mouth with the tongue and buccal musculature. In essence, "spitting" into the peak flow meter causes a dramatic false elevation in PEF.[113] Some data suggest that women need more initial coaching than men in giving maximal effort when using peak flow meters to ensure accurate assessments of PEF.[114]

A.B. needs education regarding the benefits of long-term inhaled anti-inflammatory therapy. The clinician should explain with enthusiasm that A.B.'s budesonide is an extremely effective medicine and that it is the cornerstone of her asthma management. The delayed onset and safety of ICS must be stressed as well as the requirement of regular use every day. Teaching A.B. the differences between preventers and quick relievers is essential. Showing her colored pictures, models, or a video of inflamed airways can be very helpful—these teaching aids are available from several pharmaceutical manufacturers. Likewise, a peak flow meter should be given to A.B.

and correct use ensured by observing her use of it along with establishment of green, yellow, and red zones, coupled with a written action plan developed by her asthma-care provider.[1] A.B. needs to hear from the clinicians treating her that asthma is preventable, and in the words of a title to an NIH booklet for patients, "Your asthma can be controlled: Expect nothing less." As part of comprehensive education, such a positive message from all of her caregivers, as well as carefully listening to A.B.'s concerns, can have a major impact on A.B., who has not been managing her asthma optimally.

CASE 18-13, QUESTION 2: A.B. tells the provider that she was previously instructed to place the albuterol MDI in front of her open mouth and spray rather than put the MDI in her mouth. She says she is confused because the package insert shows placement of the inhaler in the mouth. What should the clinician tell A.B.?

A.B. is correct that this is a confusing issue to many patients and health professionals. A small number of studies show that the "open-mouth" technique is better, but several other studies with SABAs show that the "closed-mouth" technique is as good as or better than putting the MDI in front of the open mouth.[1,115] In addition, the correctly performed closed-mouth technique is as efficacious with a β_2-agonist as with a spacer[107] or nebulizer.[115] One caution with the open-mouth technique is that incorrect aiming of the MDI may result in the aerosol being sprayed onto the face or into the eyes. Because the open-mouth technique has not been studied with the currently available MDIs, it is recommended that the closed-mouth technique be used because the nonchlorofluorocarbon MDIs were FDA approved using this method. Finally, regarding the HFA MDIs, special care should be followed in cleaning the actuators.[116] Healthcare professionals should stress the importance of regular MDI actuator cleaning with their patients.

CASE 18-13, QUESTION 3: For patients who are using both a bronchodilator and an anti-inflammatory inhaler, is there a preferred sequencing of the inhalers?

For patients who have several inhalers, questions regarding sequencing of the inhalers are frequently asked. First, there is no well-documented evidence that outcomes are better using, for instance, a SABA or an anti-inflammatory agent first. A commonsense approach is that using a SABA first and then an anti-inflammatory second has some appeal (i.e., quick relief and theoretically enhanced penetration of the anti-inflammatory). However, as discussed previously, SABAs are preferred for as-needed use (and before exercise) and should not be used on a long-term scheduled basis. Thus, if a patient is not symptomatic at the time the anti-inflammatory is scheduled, current literature suggests that the patient inhales only the anti-inflammatory agent. Because time is limited in counseling patients and teaching them correct inhalation technique, the purpose of each medication (controllers vs. quick relievers) and the need for strict adherence to controller therapies are far more important than spending precious time on the sequencing of inhalers.

NOCTURNAL ASTHMA

CASE 18-14

QUESTION 1: R.R., a 41-year-old man, presents to the clinic with a history of coughing and shortness of breath that awakens him at least two nights a week. Most mornings on awakening, he complains of chest tightness. He has a history of asthma since childhood and currently is managed with beclomethasone HFA 160 mcg BID via a spacer and albuterol (90 mcg/puff) two puffs every 6 hours PRN and before exercise. R.R.'s morning PEF is consistently in the yellow zone, usually at about 400 L/minute (personal best, 600 L/minute), whereas the evening PEF is consistently 550 to 600 L/minute. What treatment should be recommended?

Many patients with asthma complain of symptoms that awaken them in the night or occur on awakening in the morning. Morning cough with or without bronchospasm may be a clue to nocturnal asthma. Although nocturnal asthma may be appropriately viewed as simply another manifestation of airway inflammation, it is so common and troublesome among asthmatic patients that it deserves special note. Circadian rhythm in PEF is exaggerated in patients with asthma. The difference in PEF in nonasthmatic patients averages about 8% between 4 PM (maximal airflow) and 4 AM (minimal airflow), but in patients with asthma, the average variation can be as high as about 50%.[117] Several mechanisms account for this diurnal variation in PEF. The following are examples of factors that contribute to nocturnal asthma: increased release of inflammatory mediators,[117] increased activity of the parasympathetic nervous system, lower circulating levels of epinephrine, and lower levels of serum cortisol (lowest at about midnight). In addition, for patients whose asthma is triggered by gastroesophageal reflux, this problem is worse at night, but treatment of this problem generally provides only minimal improvement in asthma management.[118]

The initial approach to managing nocturnal symptoms is the same as that for overall long-term therapy of persistent asthma, including adequate anti-inflammatory agents.[1,117] ICS are often effective in eliminating or reducing nocturnal asthma, including symptoms and the drop in PEF. If low-to-medium dosages (i.e., correctly inhaled every day) do not eliminate symptoms, combination therapy with LABA (salmeterol, formoterol) is indicated. Also, the basic asthma treatment principle of good control of concomitant rhinitis and environmental control, especially in the bedroom (e.g., house dust mites, household pets), should be considered in the patient with nocturnal asthma symptoms.

Because asthma is primarily an inflammatory disease and nocturnal symptoms are largely caused by airway inflammation, the first drug therapy concern in R.R. is to ensure that he is strictly adhering to his beclomethasone therapy and demonstrating excellent inhalation technique. If his use of the medication is optimal, a reasonable approach would be to add LABA therapy, because he is already at a medium ICS dosage.

As part of optimal management of nocturnal asthma, R.R. also should be asked about avoiding or minimizing exposure to his asthma triggers (e.g., if he is allergic to cats, is there a cat in the bedroom?). Follow-up visits for R.R. should verify that the early morning PEF and evening PEF are staying in the green zone and that symptoms, both during the night and on awakening in the morning, have been eliminated.

DRUG-INDUCED ASTHMA

CASE 18-15

QUESTION 1: M.B., a 32-year-old woman with asthma, asks her clinician which over-the-counter medications would be preferred for minor aches and pains. M.B. says that she is very sensitive to aspirin (causes severe wheezing).

The clinician should counsel the patient regarding the fact that patients with asthma who are aspirin sensitive often react to other nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen by developing asthma symptoms with the first dose. The healthcare professional should suggest acetaminophen. If M.B. says that acetaminophen does not give adequate relief of her pain, other options are salsalate or consultation with a board-certified allergist with experience in aspirin and NSAID desensitization.[119] The clinician should also suggest consultation with an allergist regarding evidence that cyclooxygenase-2 (COX-2) inhibitors are safe in aspirin-sensitive asthma.[120] This case also points out the need for health professionals to pay close attention to patient use of nonprescription medications. Although drug-induced asthma may present as relatively mild symptoms in some patients, fatal asthma caused by medicinal agents has been reported numerous times. The most extensive literature on drug-induced asthma involves NSAIDs and β-blockers. Other drugs and drug preservatives also can induce symptoms of asthma, but because the topic is beyond the scope of this chapter, the reader is referred to other sources[121,122] for further discussion.

The percentage of asthma patients reported to be aspirin sensitive ranges from 4% to 28%. Clinical manifestations of aspirin sensitivity include rhinorrhea, mild wheezing, or severe, life-threatening shortness of breath. Once the reaction has occurred, there is a refractory period of 2 to 5 days.[123] If an asthma patient is aspirin sensitive, it is likely that the patient also will react to most other NSAIDs. Aspirin and other NSAIDs share common mechanisms involving the arachidonic acid pathways, including inhibition of cyclooxygenase, which results in more rapid synthesis and overproduction of leukotrienes.[124] Not surprisingly, because leukotrienes are an important part of the mechanism of NSAID-induced asthma, inhibitors of 5-lipoxygenase such as zileuton are generally, but not always, effective in blocking this response.[123] Similarly, leukotriene receptor antagonists such as zafirlukast and montelukast are generally, but not always, effective in blocking aspirin-induced asthma.[125] Because most patients with asthma do not react to aspirin and other NSAIDs, the NIH guidelines recommend avoiding these agents only in patients with known sensitivity.[1] In addition, patients with severe-persistent asthma or nasal polyps should be counseled regarding the risks associated with these drugs. In patients with known sensitivity, acetaminophen or salsalate is recommended for headaches and relatively minor pain.[1] For patients who are sensitive but who need to take aspirin (e.g., after myocardial infarction [MI]) or an NSAID (e.g., arthritis), it is possible to desensitize the patient, and daily use then prevents further reaction.[119]

When discussing drug-induced asthma, the other major consideration is β-blockers. These agents should be used with great caution in patients with asthma. Because even β_1-adrenergic blockers lose selectivity as dosages are increased, they, as well as nonselective β-blockers, should be avoided in most patients. Furthermore, ophthalmic timolol has been reported several times to cause fatal asthma and should absolutely be avoided in patients with a history of asthma.[126] Other β-blocker eye drops (e.g., betaxolol) have been reported to have less propensity to induce asthma, but all have some risk.[127]

Two notable exceptions to using β-blockers in patients with asthma are patients who are post-MI and patients with heart failure.[128,129] Because β-blockers prolong life after an MI and improve the care of patients with heart failure, benefits versus risks should be weighed. Risks outweigh benefits if a patient has severe-persistent asthma.[128,129] If a post-MI patient has intermittent asthma or well-controlled mild-persistent or moderate-persistent[128,129] asthma with optimal management, a low dosage of atenolol 50 mg/day is a reasonable consideration in which benefits may outweigh risks.[129] Patients with asthma have been shown to respond to inhaled β_2-agonists when receiving this dosage of atenolol.[129] Although low dosages of β-blockers are not proven to prolong life after an MI, some studies suggest efficacy of lower dosages. For patients with heart failure, metoprolol CR/XL is the cardioselective β-blocker approved in the United States, whereas carvedilol, which has nonselective β-blocker as well as α-blocking properties, can worsen asthma symptoms or cause fatal asthma.[130]

If a patient with asthma is given a β-blocker and initially reports no symptoms, subsequent exacerbations may not respond well to administration of usual doses of a β-agonist. The drug of choice for β-blocker–induced bronchospasm is ipratropium.[129] A more subtle risk with β-blockers involves the adult with allergic rhinitis and a family history of asthma. If this individual is given a β-blocker for hypertension, symptoms of asthma could be induced, especially if another trigger is introduced such as running in cold, dry air.

OUTCOMES

CASE 18-16

QUESTION 1: C.C. is a 36-year-old woman admitted to the hospital for asthma. This is her second hospitalization in the past 2 years, and she has had three ED visits during the same period. She also complains of nocturnal awakenings at least four nights per week and is bothered that she is gaining weight because she cannot exercise. Lack of exercise is also troubling her because her 5-year-old daughter wants her to go outside and play with her. C.C. has been inhaling fluticasone 44 mcg one puff BID without a spacer for years along with frequent PRN albuterol. C.C. carefully controls her home environment. What could her clinicians do to improve her outcomes, including quality of life?

C.C. needs a reassessment of her long-term management considering her very poor outcomes during the past 2 years. First, her clinicians need to establish a partnership with her in education regarding asthma and its management. Clearly, she needs a dosage adjustment with her anti-inflammatory therapy because her dosage is too low and she is experiencing symptoms of poor asthma control. Given her recent history, she should be treated initially with medium-dose ICS and a LABA (e.g., combination budesonide–formoterol, combination mometasone–formoterol, or combination fluticasone–salmeterol). C.C. should have the importance of daily controller therapy stressed, including the need for strict adherence and proper inhalation technique. C.C. needs a written asthma action plan and an emergency supply of prednisone (i.e., to use when her PEF is in the red zone and

---

unresponsive to albuterol). C.C. should be told to expect a reduced need for albuterol.

Numerous studies have documented that applying the principles of the evidence-based guidelines[1] results in improved clinical outcomes, and many of these studies have been summarized in EPR-3.[1] Several studies in the United States have documented that pharmacists who are highly knowledgeable of EPR-3 and who work closely with patients and physicians improve outcomes, including reduced ED visits and hospitalizations.[131–135] These successful studies involved highly motivated pharmacists, who were asthma experts based in university-affiliated clinics or in large private health maintenance organizations.

A randomized controlled trial based in community pharmacies in Canada with specially trained pharmacists has also shown very positive outcomes for patients with asthma.[136] Another randomized controlled trial based in chain drug stores in the United States with staff pharmacists did not show a benefit related to attempts at asthma care.[137] Unfortunately, the level of training and incentives did not appear optimal, and the authors pointed out that the staff pharmacists were “not universally enthusiastic” about the program. The authors also described their intervention as "cumbersome" for the pharmacists. Further study is needed to assess asthma care in this setting when pharmacists are optimally trained, given appropriate incentives, and enthusiastic about the program. Many studies outside the United States have shown that community pharmacists are helpful in asthma management.[138]

When assessing the effect of comprehensive management on clinical outcomes, quality-of-life measures should be assessed (a validated questionnaire [the Asthma Control Test] is shown in EPR-3[1]) as well as reduction in ED visits and hospitalizations.[1] To achieve optimal outcomes, attention to each of the four major components of management is required (objective assessment, environmental control, pharmacologic therapy, and patient education as a partnership). Examples of areas that pose special challenges for inner-city patients include psychosocial factors, underuse of controller medications, and passive cigarette smoke.[139–142] As part of overall management to improve outcomes, studies have emphasized again the importance of good inhalation technique with ICS and education in the use of peak flow meters.[143,144]

CASE 18-16, QUESTION 2: C.C. returns to the clinic in 2 months and is elated because she is sleeping through the night and not waking up with shortness of breath. In addition, she is beginning to exercise again, which makes her and her child very happy. C.C. has had no further ED visits. What should the clinician do at this point?

Optimal asthma management that improves outcomes is a continuous process of education and reassessment of the overall therapy. Observation of C.C. using her peak flow meter and inhalation devices on each clinic visit is important and should be routine. Having C.C. verbalizes her understanding of the role of the ICS plus LABA versus albuterol and the action plan with "crisis" prednisone is important. Despite her current optimism, asking C.C. about her current asthma concerns is important. During the next month or two, a trial of slowly stepping down the ICS dosage to a medium dose should be attempted. Finally, C.C. needs continued partnership with her clinician.

CASE 18-16, QUESTION 3: C.C. is in the clinic 2 years later, reflecting with her clinician about her total elimination of ED visits and hospitalizations as well as her improved quality of life. Her management initiated 24 months ago has continued, including environmental control, controller therapy tailored for her, PRN albuterol, early morning PEF monitoring, and partnership with her clinician. Unfortunately, C.C. forgot to get an influenza vaccine last October and became ill with influenza in early March. Although this episode only slightly worsened her asthma symptoms, when she was almost recovered from the flu, she went to the grocery store and breathed secondhand smoke unexpectedly. In addition, early spring tree and grass pollen was affecting her allergic rhinitis. By the time she got back to her house, she was wheezing and her PEF was in the yellow zone, but it responded to three puffs of albuterol. C.C. asks what she should have done if this series of events had resulted in her PEF decreasing to the red zone.

C.C. needs to be re-educated regarding the action plan based on symptoms and PEF values. Referring back to the written plan for doses of albuterol and, if needed, oral corticosteroid therapy is important. Emphasizing the need for annual influenza vaccination in October is important. In addition, patients with asthma ≥19 years of age should receive pneumococcal vaccine, and patients ≥65 years of age should receive pneumococcal conjugate vaccine (see Chapter 64 for more details) Reinforcement of the importance of continued preventive therapy that has given such remarkable success is appropriate for C.C. and reassuring her that despite this minor setback, she is in control of her asthma. The clinician should continue to work with her to further tailor the therapy, including control of rhinitis, to maintain optimal outcomes at the lowest dosages and the simplest possible regimen. Research has further emphasized the goal of simplified regimens and achieving the lowest effective doses of anti-inflammatory therapy.[145,146]

COMPLEMENTARY ALTERNATIVE THERAPIES

CASE 18-16, QUESTION 4: C.C. is in the clinic a few months later. She is continuing to have excellent control of her asthma and allergic rhinitis. C.C. asks her healthcare professional for her opinion of herbal remedies for asthma as well as other nontraditional approaches to treatment.

Complementary and alternative approaches that have been used in the treatment of asthma include black tea, coffee, ephedra, marijuana, dried ivy leaf extract, acupuncture, meditation, and yoga.[1,147,148] Despite the widespread use of alternative medications for chronic conditions, the clinician should discuss with C.C. that there is no established scientific basis for their use in the management of asthma.[1] One study found that use of herbal treatments was associated with reduced adherence to ICS therapy and poor outcomes among inner-city patients with asthma.[149]

Complementary alternative medicine cannot be recommended as a substitute for the drug therapy recommended by EPR-3 and other medical literature based on randomized controlled studies. While not a “complementary alternative” therapy, one nondrug marketed treatment, bronchial thermoplasty, has been demonstrated to be efficacious in the management of severe, refractory asthma.[150]

Chronic Obstructive Pulmonary Disease

Timothy R. Hudd and Kathy Zaiken

CORE PRINCIPLES	CHAPTER CASES
① Chronic obstructive pulmonary disease (COPD) is characterized by chronic airflow limitation and a range of pathologic changes in the lung, some significant extrapulmonary effects, and important comorbidities that may contribute to the severity of the disease in individual patients. Cigarette smoking is the major risk factor for COPD, and most cases of COPD are attributed to a current or past history of cigarette smoking.	**Case 19-1 (Question 1)**
② Inhalation of noxious particles or gases, such as cigarette smoke, leads to the activation of resident immune and parenchymal cells, which in turn recruit additional inflammatory cells from the systemic compartment into the lung. The exact mechanisms responsible for the pathogenesis of COPD are not entirely clear, but likely involve activation of the innate and adaptive immune system, leading to chronic inflammation.	**Case 19-2 (Question 2)**
③ As COPD progresses, additional systemic consequences can arise, including cachexia, cardiac and skeletal muscle dysfunction, osteoporosis, depression, and anemia. Pulmonary rehabilitation is recommended to address these systemic manifestations.	**Case 19-2 (Question 5)**
④ The diagnosis of COPD is based on the presence of risk factors (usually including smoking), clinical symptoms, and airflow obstruction based on spirometric testing. Generally, COPD manifests in the sixth decade of life (or later) with symptoms of cough, wheeze, or dyspnea on exertion. The severity of disease is based on a grading system, which then guides therapy.	**Case 19-1 (Questions 1, 2)**
⑤ The only interventions that reduce mortality in COPD are smoking cessation, oxygen therapy for patients with severe hypoxemia at rest, and lung volume reduction surgery for very select patients with advanced emphysema. Medications are an important component of therapy and are aimed at alleviating symptoms and maximizing quality of life.	**Case 19-1 (Question 3)**
⑥ Bronchodilators are central to the symptomatic management of COPD and include short-acting and long-acting β_2-agonists, short-acting and long-acting anticholinergic agents, and theophylline.	**Case 19-2 (Questions 1, 3, 4), Case 19-3 (Questions 2, 3)**
⑦ Combination long-acting bronchodilator therapy or daily use of inhaled corticosteroid in combination with a long-acting β_2-agonist may be	**Case 19-2 (Question 3)**

	effective in patients with advanced COPD, whereas systemic corticosteroids are only advocated for short-term use owing to the risk of adverse effects.	
8	Antibiotic use in the setting of an acute exacerbation should be made based on the presence of the following symptoms: increased dyspnea, sputum volume, and sputum purulence.	**Case 19-3 (Question 1)**
9	Supplemental oxygen is currently initiated for severe hypoxemia, defined as an oxygen saturation less than 88% or Pao_2 of 55 mm Hg or less (oxygen saturation < 90% or $\text{Pao}_2 \leq 59$ mm Hg in the presence of polycythemia or clinical evidence of pulmonary hypertension, e.g., peripheral edema).	**Case 19-4 (Question 1)**
10	Lung volume reduction surgery, which involves the surgical removal of approximately 30% of the volume of each lung, can significantly improve quality of life, exercise tolerance, and mortality in selected patients with COPD.	**Case 19-4 (Question 2)**

Definitions

Chronic obstructive pulmonary disease (COPD) is a common preventable and treatable airway disorder characterized by symptoms such as dyspnea, chronic cough, and sputum production along with persistent airflow limitation that is not fully reversible.[1,2] Airflow limitation is often progressive and associated with an enhanced chronic inflammatory response in the airways and the lung to noxious particles or gases.[1] Emphysema and chronic bronchitis are two commonly used terms that reflect the spectrum of this disease and are often used as pathologic subtypes of COPD. More recent definitions have transitioned away from these terms, as both pathologic subtypes likely contribute to airflow limitation in patients with COPD.[1]

In 2001, the National Institutes of Health (NIH) and the World Health Organization (WHO) collaborated to develop the Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines.[1] These guidelines address a wide variety of topics related to COPD, including current concepts of pathophysiology, and make recommendations regarding diagnosis and treatment. The guidelines are updated yearly, represent an international effort, and are based on the strength of the evidence supporting them.

Asthma is a separate obstructive airway disorder with features similar to COPD. However, airflow limitation and symptoms such as wheezing, cough, dyspnea, and chest tightness are usually episodic and reversible. Some patients may present with features from both conditions, with 15% to 20% of patients sharing a dual diagnosis of asthma and COPD.[3] The term "Asthma-COPD Overlap Syndrome" has been recently described to help clinicians better identify and manage these patients.[3]

Epidemiology

COPD affects an estimated 15 million Americans and is the fourth leading cause of death worldwide.[1,4,5] In 2010, associated US health care costs were approximately $49.9 billion dollars, including $29.5 billion in direct health care expenditures.[2] COPD exacerbations are the most significant contributor to the cost burden of the disease accounting for approximately 50% to 75% of all costs.[5]

COPD is also a leading cause of disability in the United States.[6] Surveillance data from the 2013 Behavioral Risk Factor Surveillance System found that patients with COPD were more likely to be unable to work (24.3% vs. 5.3%), have difficulty walking or climbing stairs (38.4% vs. 11.3%), and report limitations with daily activity because of health problems (49.6% vs. 16.9%) compared with adults without COPD.[4]

The prevalence of COPD and associated costs are expected to continue to rise over the next few decades, at least in part due to the increased life expectancy of the general population and advanced age of patients who began smoking earlier in life.[1,6–8] Historically, the prevalence of COPD and related mortality was reported to be greater in men than in women. However, COPD is now believed to affect both men and women equally.[1] In recent years, concerted efforts have been made to increase awareness around the rising prevalence of COPD among women.[9] Reason for this increase is likely multifactorial and may be due to changes in smoking patterns among women over the past century, and a growing body of evidence suggests women may be more vulnerable to the adverse effects of smoking.[10]

Risk Factors

Cigarette smoking is the major risk factor for COPD and most cases of COPD are attributed to a current or past history of cigarette smoking.[1] Importantly, with more severe disease, the relevance of cigarette smoking as a risk factor becomes even more pronounced. Evidence exists that among patients with severe emphysema approximately 99% have a history of regular cigarette smoking.[11] It should be noted that only a few smokers develop clinically significant COPD, suggesting that other risk factors may be important cofactors with smoking in COPD development. Such factors include occupational dusts and chemicals,[12–15] indoor and outdoor air pollution,[16–18] and certain infections, including respiratory viruses[19] as well as infection with human immunodeficiency virus.[20] It is possible that such factors may upregulate the inflammatory response of the lungs to cigarette smoke.[19,20] Genetic factors are also likely to be important, although precise genetic characteristics have not yet been elucidated.[21–23] One exception is α_1-antitrypsin deficiency, which affects less than 2% of patients with emphysema. Affected individuals have an inherited deficiency of this protective antiprotease and are at much greater risk of developing emphysema than the general population.[24]

The risk of COPD from cigarette smoking is related to an accelerated loss of lung function. After age 35, nonsmokers experience a decline in forced expiratory volume in the first second of expiration (FEV_1) of about 20 to 30 mL/year. In smokers, the decline may be 50 to 120 mL/year.[25] A model of the annual decline in lung function in nonsmokers, smokers, and susceptible smokers is illustrated in Figure 19-1.

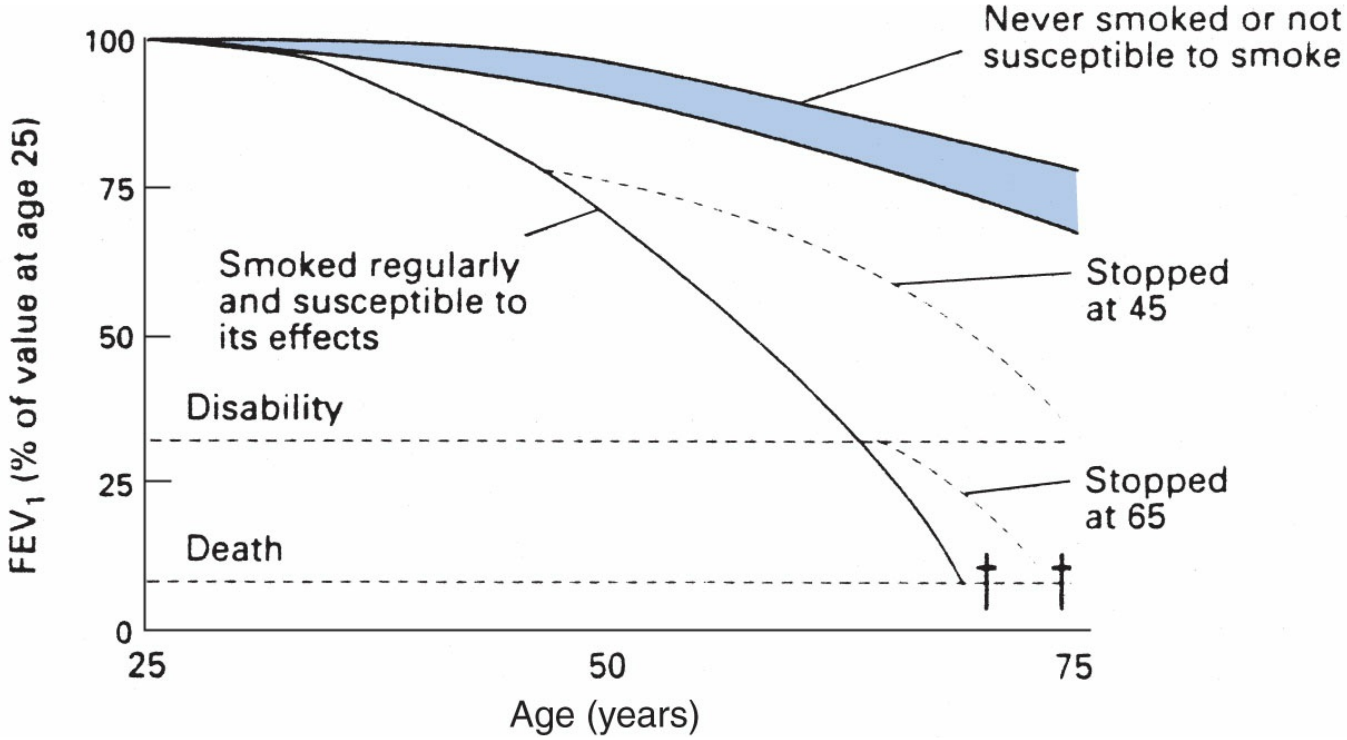

Figure 19-1 Model of annual decline in FEV_1 with accelerated decline in susceptible smokers. On stopping smoking, subsequent loss is similar to that in healthy nonsmokers. (Fletcher C, Peto R. The natural history of chronic airflow obstruction. BMJ. 1977;1:1645.)

Pathogenesis

The exact mechanisms responsible for the pathogenesis of COPD are not entirely clear, but likely involve activation of the innate and adaptive immune system leading to chronic inflammation. In general, inhalation of noxious agents, such as cigarette smoke, leads to the activation of resident immune and parenchymal cells, which in turn recruit additional inflammatory cells from the systemic compartment into the resident tissue and airway (Fig. 19-2).

The activation and recruitment of immune cells is largely mediated through the production and release of cytokines and chemokines (Table 19-1). Recent evidence also supports a role for oxidant stress as a disease mediator.[26,27] The consequences of an oxidant-rich environment include the activation of inflammatory genes, inactivation of antiproteases, stimulation of mucus secretion, and increases in plasma exudate.

The most well studied cause of COPD, and particularly emphysema, relates to protease–antiprotease imbalance. In this setting, inflammation promotes the production and release of proteases from inflammatory and parenchymal cells. When the local concentration of antiproteases becomes overwhelmed, proteases go unchecked and destroy the major connective tissue components in the lung, such as elastin, leading to the irreversible loss of alveoli. The classic example of this occurs in patients with α_1-antitrypsin deficiency.

Although the traditional idea of disease pathogenesis focuses on smoking-related lung injury, more recent hypotheses suggest that another important component of disease pathogenesis may involve inadequate lung repair. Indeed, there is evidence that normal lung homeostatic mechanisms are altered in COPD. This may involve inadequate production of growth factors as well as altered regulation of apoptosis, or programmed cell death.[28]

Pathophysiology

The airflow obstruction caused by COPD is usually progressive and is attributed to pathologic changes in the lung that affect the proximal airways, peripheral airways, lung parenchyma, and pulmonary vasculature.[29] Alterations in tissue structure are caused by chronic inflammation that involves recruitment of inflammatory cells into the lung, as well as structural changes that result from repeated injury and tissue remodeling. The magnitude of structural changes and tissue dysfunction varies among patients and is often distinguished by two major phenotypes that include chronic bronchitis and emphysema. Chronic airflow limitation can result from both of these processes. The GOLD or most recent American Thoracic Society (ATS) and European Thoracic Society guidelines[30] do not distinguish between these two entities; however, the classic definitions and pathophysiologic features are described here to aid in a better understanding of the disease process.

In the simplest view, bronchitis is inflammation of the bronchioles. The clinical definition from the ATS for chronic bronchitis is “the presence of chronic productive cough for 3 months in each of two consecutive years in a patient in whom other causes of chronic cough (e.g., asthma, congestive heart failure, gastroesophageal reflux) have been excluded.”[31] Emphysema is described as “abnormal permanent enlargement of the airspaces distal to the terminal bronchioles, accompanied by destruction of their walls and without obvious fibrosis.” The degree of impairment of the small airways (bronchioles) or the lung parenchyma (alveoli and supporting structures) directly influences tissue dysfunction and the clinical symptoms of the patient.

LARGE (CENTRAL) AND SMALL (PERIPHERAL) AIRWAYS

The large airways, which include the trachea and first generations of the bronchi, are a major site of inflammation and mucus hypersecretion. This results from an increase in numbers (hyperplasia) and enlargement (hypertrophy) of the submucosal glands and mucus-producing goblet cells within the surface epithelium.[32,33] Overproduction of mucus in the large airways results in a chronic productive cough, as observed in chronic bronchitis, but this does not have a major impact on airflow limitation. Mucus hypersecretion coupled with impaired ciliary function reduces mucociliary clearance, increases the accumulation of secretions, and enhances the risk of bacterial colonization in an otherwise sterile environment.[34] As a result, recurrent infections often occur owing to the inability to clear pathogens.

Table 19-1

Inflammatory Cells and Mediators in Chronic Obstructive Pulmonary Disease (COPD)

Cell	
Neutrophils	↑ in sputum of normal smokers. Further ↑ in COPD and related to disease severity. Few neutrophils are seen in tissue. May be important in mucus hypersecretion and through release of proteases.
Macrophages	Greatly ↑ numbers in airway lumen, lung parenchyma, and bronchoalveolar lavage fluid. Derived from blood monocytes that differentiate within lung tissue. Produce increased inflammatory mediators and proteases in patients with COPD in response to cigarette smoke and may show defective phagocytosis.
T lymphocytes	Both CD4+ and CD8+ cells are increased in the airway wall and lung parenchyma, with ↑CD8+:CD4+ ratio. ↑CD8+ T cells (Tc1) and Th1 cells that secrete interferon-γ and express the chemokine receptor CXCR3. CD8+ cells may be cytotoxic to alveolar cells, contributing to their destruction.
B lymphocytes	↑ in peripheral airways and within lymphoid follicles, possibly as a response to chronic colonization and infection of the airways.
Eosinophils	↑ eosinophil proteins in sputum and ↑ eosinophils in airway wall during exacerbations.
Epithelial cells	May be activated by cigarette smoke to produce inflammatory mediators.
Mediators	
Chemotactic factors	Lipid mediators: e.g., leukotriene-B_4 (LTB_4) attracts neutrophils and T lymphocytes. Chemokines: e.g., interleukin-8 (IL-8) attracts neutrophils and monocytes.
Proinflammatory cytokines	Cytokines, including tumor necrosis factor-**α** (TNF-**α**), IL-1**β**, and IL-6 amplify the inflammatory process and may contribute to some of the systemic effects of

	COPD.
Growth factors	E.g., transforming growth factor-**β** (TGF-**β**) may induce fibrosis in small airways.

Source: Global Initiative for Chronic Obstructive Lung Disease (GOLD). Global Strategy for the Diagnosis, Management and Prevention of COPD (Updated 2010). http://www.goldcopd.org. Accessed July 27, 2015.

The peripheral airway is composed of the smaller bronchi down to the terminal bronchioles, the smallest branches in the lung that are not involved in gas exchange. The extent of inflammation, fibrosis, and airway exudate in the peripheral airway correlates best with the reduction in airflow as measured by a decrease in FEV_1 or the FEV_1 to forced vital capacity (FVC) ratio.[35] Chronic obstruction of the peripheral airway also results in air-trapping on expiration, which contributes to hyperinflation. Hyperinflation places the respiratory muscles at a mechanical disadvantage and further reduces respiratory capacity. Hyperinflation can become more pronounced during exercise, leading to dyspnea and decreased exercise capacity. It is now known that hyperinflation can occur early in the course of COPD and is an important cause of exertional dyspnea.[36]

PARENCHYMAL DESTRUCTION

The terminal bronchioles lead directly to the alveolar ducts and sacs, the major site where gas exchange occurs. Emphysema is characterized by the destructive loss of alveolar walls and enlargement of the terminal airspaces, resulting in a loss of gas-exchanging surface area.[34,37] In advanced cases, large, balloon-shaped bullous lesions may develop. Rupture of these bullae (pneumothorax) can lead to collapse of lung segments (pneumothorax).

SIGNIFICANT COMORBID ILLNESS

In the later stages of disease, chronic hypoxemia causes persistent vasoconstriction in the lung vascular bed, particularly the small pulmonary arteries. This can result in permanent structural alteration of the blood vessels, causing intimal hyperplasia and smooth muscle hypertrophy.[38] The loss of pulmonary capillaries in emphysema can also contribute to increased pulmonary vascular pressures. The cumulative impact of vascular changes can result in progressive pulmonary hypertension and, eventually, right-sided cardiac failure (cor pulmonale).

As COPD progresses, additional systemic consequences can arise, including cachexia, skeletal muscle dysfunction, osteoporosis, depression, and anemia. The cause of these additional systemic disease processes is not entirely clear but likely involves the dynamic interplay of progressive respiratory dysfunction, lung and systemic inflammation, side effects from medication use, and physical debilitation. In summary, although COPD is primarily a disease of the large and small airways and adjacent alveolar structures, it also includes important systemic consequences. The clinical consequences of the morphologic and pathophysiologic alterations include progressive dyspnea on exertion, chronic cough and sputum production, increased risk for respiratory infections, deconditioning, and an overall reduction in quality of life.

COMPARISON WITH ASTHMA

COPD and asthma are common obstructive airway disorders, and both illnesses can coexist in the same patient. Nevertheless, these conditions should be considered as separate and distinct entities (Table 19-2). For example, although inflammation is a key component of both conditions, the pattern of inflammation differs significantly (Table 19-3). As a result, the pathophysiologic consequences, patient symptoms, and response to medications typically differ. Asthma is generally not progressive, and symptoms and airflow obstruction are often completely reversible. Patients with asthma respond well to antiinflammatory medication, including inhaled corticosteroids (ICS). Furthermore, in the absence of an acute exacerbation, significant gas exchange abnormalities are uncommon. COPD, on the other hand, is a progressive and often fatal disorder. Although bronchodilators are helpful in COPD, the degree of bronchodilator reversibility is typically less than that seen in asthma. In addition, the beneficial effects of antiinflammatory medication, including ICS, are much more modest. Patients with COPD, particularly those with emphysema, have substantial derangements in pulmonary gas exchange even at baseline.

Table 19-2

Clinical Features of Asthma, COPD, and ACOS

Clinical Feature	COPD	Asthma	Asthma-COPD Overlap Syndrome (ACOS)
Age of onset	>40 years of age	Childhood, but can occur at any age	Usually ≥40 years of age, but may have had symptoms in childhood or adolescence
Possible symptoms	Dyspnea, chronic cough, sputum production	Dyspnea, cough, wheeze, chest tightness	Mixed symptoms
Symptom pattern	Persistent and slowly progressive. Present daily, worse with exertion or exercise.	Vary day to day and may be episodic based on trigger exposure. Often worse at night or early morning.	Persistent and worse with exertion though variability may exist
Risk factors	History of chronic exposure to cigarette smoke, biomass fuels, or noxious particles and gases α_1-antitrypsin deficiency (<2% of cases)	Atopic conditions (i.e., allergies, eczema, etc.) Family history of asthma	History of asthma with chronic exposure to cigarette smoke, biomass fuels, or noxious particles and gases

Post-bronchodilator FEV_1 reversibility[a] FEV_1/FVC ratio	Usually little to no change FEV_1/FVC < 70%	Reversible and may be normal between symptoms	Airflow limitation is usually not fully reversible and often varies over time
Chest X-ray	Hyperinflation	Usually normal	Hyperinflation

[a]Reversibility defined as an increase in FEV_1 of >200 mL and 12% from baseline measure after inhalation of a short-acting β_2-agonist.

α_1-ANTITRYPSIN DEFICIENCY

The best-characterized antiprotease in the lung is α_1-antitrypsin. This serum glycoprotein is primarily produced in the liver and works by binding to and neutralizing proteases. As described previously, cigarette smoke can activate and attract inflammatory cells into the lung, thereby promoting the release of proteases such as elastase. Cigarette smoke can also inactivate endogenous protease inhibitors, including α_1-antitrypsin, further supporting protease activity and increasing the risk of tissue damage. This risk of tissue damage is greatly accentuated in patients with α_1-antitrypsin deficiency. α_1-Antitrypsin deficiency occurs in less than 2% of all COPD cases. Clinically significant disease is usually associated only with severe deficiency (i.e., serum α_1-antitrypsin levels < 45 mg/dL; normal > 150 mg/dL). The diagnosis of α_1-antitrypsin deficiency is made by measuring circulating serum α_1-antitrypsin levels, followed by phenotype analysis.[39] The PiM allele confers production of the fully functional protein. Accordingly, a homozygous PiMM individual will produce a functional protein with normal plasma concentrations. Other gene types include, but are not limited to, PiS (normal serum levels of a poorly functioning enzyme), PiZ (an active form but poorly secreted, leading to low circulating levels), and Pi null (gene polymorphism leads to production of a truncated protein and undetectable serum levels of functional protein). Different allele pairs can exist. PiMZ and PiSZ are heterozygous disorders, and PiSS is a homozygous phenotype, all with greater than 35% of normal enzyme activity and a relatively low risk of developing emphysema. PiZZ is a rare homozygous disorder characterized by accelerated lung destruction and serum α_1-antitrypsin levels approximately 15% of normal. In these rare patients, the disease develops as early as age 20, but more typically it occurs in the fourth to fifth decade of life.

Replacement therapy is available for patients with COPD with documented α_1-antitrypsin deficiency and emphysema. Patients who do qualify typically receive weekly intravenous infusions of α_1-antitrypsin to maintain acceptable antiprotease activity and minimize the progression of lung disease. This therapy is very expensive, and it is not well tolerated by some (fever, chills, allergic reactions, flulike symptoms). Currently, no placebo-controlled, randomized trials have documented the efficacy of replacement therapy. Case–control studies, however, suggest the replacement therapy may improve outcomes in patients with α_1-antitrypsin deficiency, documented emphysema, and an FEV_1 between 35% and 60% of predicted.[24] Three different formulations of α_1-antitrypsin are available: Aralast, Prolastin, and Zemaira. No clinically significant differences exist among these preparations. Because the α_1-antitrypsin products are derived from pooled human plasma, there are also associated risks for the transmission of infectious diseases (e.g., viral infections and Creutzfeldt–Jakob disease). Overall, use of the α_1-antitrypsin replacement therapy remains controversial, and some have argued that this therapy cannot be recommended based on a lack of proven clinical benefit and high cost of treatment.[40]

DIAGNOSIS AND PATIENT ASSESSMENT

The diagnosis of COPD is based on the presence of risk factors (generally smoking), clinical symptoms, and airflow obstruction on spirometric testing.[1] Generally, individuals with COPD present in the sixth decade of life (or later) with symptoms of cough, wheeze, or dyspnea on exertion.[30] Patients usually have at least a 10-pack-year history (e.g., averaging one pack of cigarettes a day for 10 years) of cigarette smoking. Because the severity of COPD is related to the cumulative exposure to cigarette smoke, patients with more severe disease are likely to be older with a heavier smoking history. Cough and sputum production may be present for many years before airflow limitation develops, but not everyone with those symptoms will develop COPD. Dyspnea on exertion may not be present until the sixth or seventh decade.

Table 19-3

Differences in Pulmonary Inflammation Between Asthma and Chronic Obstructive Pulmonary Disease (COPD)

COPD	Asthma	Severe Asthma
Cells		
Neutrophils++	Eosinophils++	Neutrophils+
Macrophages+++	Macrophages+	Macrophages
CD8+ T cells (Tc1)	CD4+ T cells (Th2)	CD4+ T cells (Th2)
		CD8+ T cells (Tc1)

Key Mediators		
IL-8, TNF-α, IL-1β, IL-6, NO+	Eotaxin	IL-8
	IL-4, IL-5, IL-13	IL-5, IL-13
	NO+++	NO++
Oxidative Stress		
+++	+	+++
Site of Disease		
Peripheral airways	Proximal airways	Proximal airways
Lung parenchyma		Peripheral airways
Pulmonary vessels		
Consequences		
Squamous metaplasia	Fragile epithelium	
Mucous metaplasia	Mucous metaplasia	
Small airway fibrosis	↑Basement membrane	
Parenchymal destruction	Bronchoconstriction	
Pulmonary vascular remodeling		
Response to Therapy		
Small bronchodilator response	Large bronchodilator response	Smaller bronchodilator response
Poor response to steroids	Good response to steroids	Reduced response to steroids

IL, interleukin; NO, nitric oxide; TNF, tumor necrosis factor.

On physical examination, patients with early COPD may not exhibit any changes.[30] Later, objective findings include the presence of a barrel chest (defined as an increase in the anteroposterior diameter of the chest), rales (defined as intermittent, nonmusical, brief crackle sounds), rhonchi (defined as continuous, musical high- or low-pitched sounds), prolonged expiratory phase, and cyanosis.[32] Symptomatic patients may present with decreased breath sounds, wheezes, or slight rales on auscultation. In advanced disease, cyanosis, edema, intercostal retractions, and pursed lip breathing may be present.[32]

Spirometry Testing

Spirometry is the gold standard measurement in assessing and monitoring obstructive lung disease and is required for a diagnosis of COPD.[1,30] In the evaluation of COPD, spirometry testing should be performed according to published guidelines, when the patient's condition is stable and after administration of two to four puffs (90 mcg/puff) of albuterol by metered-dose inhaler (MDI). During spirometry, a full breath is taken, followed by a forceful exhalation of all the air that can be exhaled (FVC). Flow rates and volumes of air that are expired at different time intervals can be recorded (Fig. 19-3). The FEV_1 is the volume of air that can be expired within the first second of an FVC maneuver. A decrease in the FEV_1/FVC ratio indicates airflow obstruction. Although the range of normal for FEV_1/FVC depends on the age, sex, and height of the patient, a value of less than 0.70 indicates airflow obstruction that is compatible with COPD.[1,30] Also, patients with COPD may have some improvement in spirometry testing with an acute bronchodilator challenge. The degree of reversibility is typically less than that seen with asthma, although up to 50% of patients with moderate to severe emphysema will have an increase in FEV^1 with acute bronchodilator challenge that meets ATS criteria as significant. In addition to being critical for making the diagnosis of COPD, spirometry also affords the best objective way to monitor disease progression and should be considered if there has been a persistent change in clinical symptoms (e.g., worsened dyspnea). Four "grades" are used to classify the degree of airflow limitation using post-bronchodilator spirometric results in patients with an FEV1/FVC <70%. The grades are as follows: GOLD 1 (Mild) FEV1 ≥= 80% Predicted, GOLD 2 (Moderate) FEV1 between ≥ 50% to 80% Predicted, GOLD 3 (Severe) FEV1 between ≥ 30% to 50% Predicted, and GOLD 4 (Very Severe) FEV1 < 30% Predicted. Deteriorating lung function is associated with increased prevalence of hospitalizations, exacerbations, and associated mortality at the population level.[1] However, FEV1 is an unreliable clinical indicator when used alone to predict exacerbation or mortality risk at the individual patient level.[1] Although optimal frequency of spirometric testing for patients with COPD is not known, some groups recommend annual monitoring to identify patients whose lung function may be declining rapidly.[1]

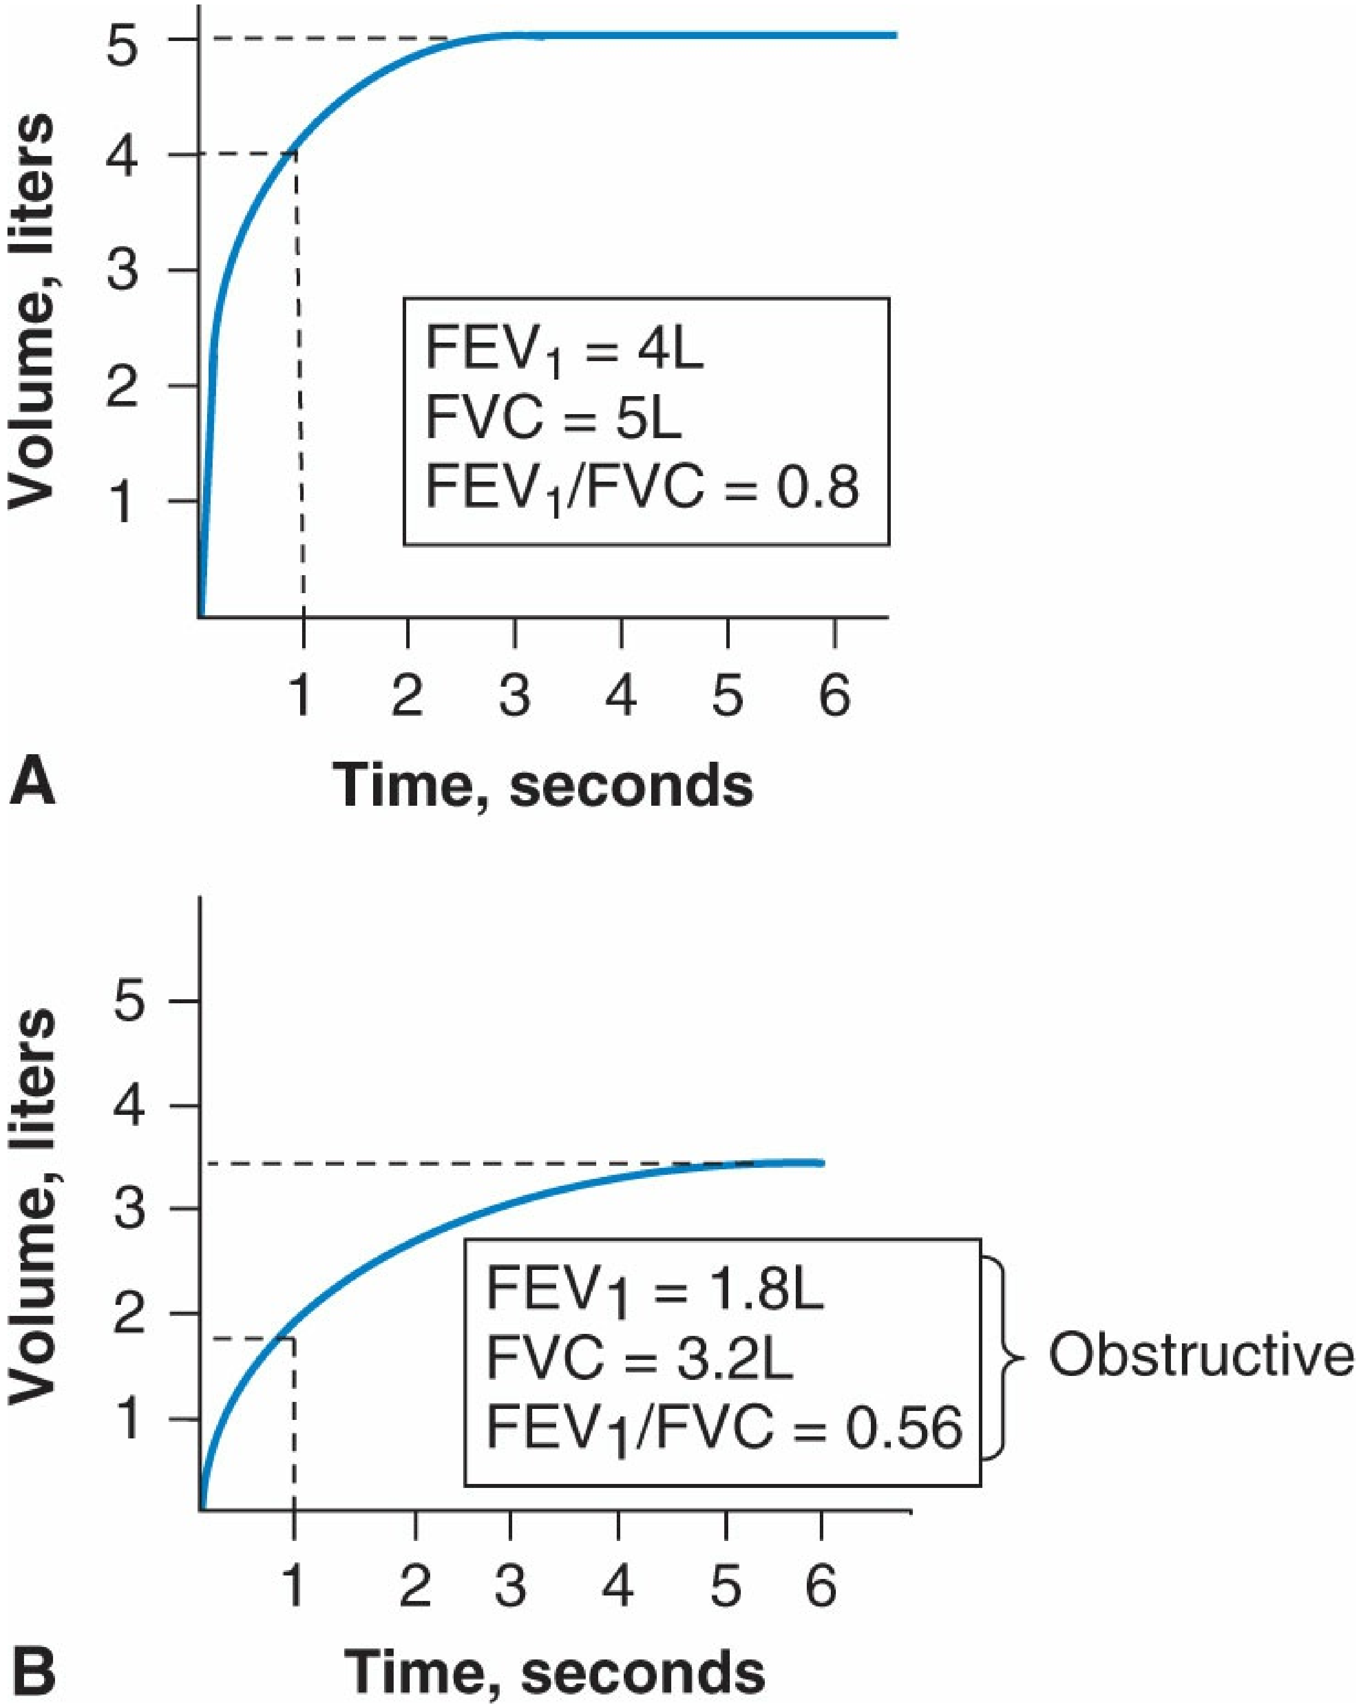

Figure 19-3 A normal spirometry tracing is shown in **A.** A spirometry tracing typical of a patient with obstructive disease is shown in **B.** Redrawn from Global Initiative for Chronic Obstructive Lung Disease (GOLD). Global Strategy for the Diagnosis, Management, and Prevention of COPD (Updated 2015). http://www.goldcopd.org Accessed July 27, 2015.

Other pulmonary function testing is sometimes used to assess patients with COPD. The determination of lung volumes, including the total lung capacity (TLC) and residual volume (RV), as well as measurements of the diffusing capacity for carbon monoxide (DLCO) may provide more detail regarding lung physiology. For example, a reduction in DLCO indicates disruption or destruction of the alveolar capillary interface and correlates with the degree of emphysema. Determination of lung volumes may be used to assess the presence of concomitant restrictive lung disease (e.g., idiopathic pulmonary fibrosis) in the case of diagnostic uncertainty. Patients with COPD typically have normal or increased lung volumes; a reduction in TLC may indicate a superimposed restrictive process. Furthermore, lung volumes and diffusion capacity are used to assess patients for surgical procedures, such as lung volume reduction surgery.[11] In most cases, however, spirometric testing is adequate to make the diagnosis of COPD and follow the course of disease.[1,30]

A chest x-ray study (CXR) is often performed during the initial assessment of patients with COPD. Because the CXR lacks sensitivity and demonstrates minimal changes until COPD is moderately severe, its main utility is in ruling out other disease processes that may be contributing to the patient's symptoms. In severe disease, the chest radiograph may indicate hyperinflation manifested by a flattened diaphragm or evidence of pulmonary arterial hypertension characterized by enlarged pulmonary arteries.

Assessing the oxygen status of a patient with COPD can be done by pulse oximetry. This should be considered in patients with dyspnea and advanced disease, and patients with evidence of right ventricular pressure overload (e.g., peripheral edema or jugular venous distension). Although a decrease in pulse oximetry (normal, $\geq 97\%$) is common in COPD, values of 88% or less are consistent with chronic respiratory failure and qualify the patient for supplemental oxygen. Arterial blood gas (ABG) determination is generally reserved for patients with severe disease (i.e., an $FEV_1 < 50\%$ of predicted). ABGs can more precisely define the oxygen status of a patient and can be used to assess whether the patient has carbon dioxide retention (normal $Pco_2 = 35–45$ mm Hg). Determining the α_1-antitrypsin concentration is indicated for patients developing COPD before age 45, and for patients who have emphysema without a significant history of cigarette smoking or who have a family history of emphysema.

Classification of Severity and Clinical Presentation

A number of methods have been proposed to categorize the severity of COPD, many of which are based primarily on the degree of airflow obstruction as assessed by the FEV_1.[30,31] However, lung function has been found to be a poor indicator of disease severity when used alone. The most recent GOLD Report utilizes symptom severity and exacerbation risk to assess COPD (Table 19-4). Comorbidities are also considered when managing these patients.[1] Patients are assigned to one of the following four groups when classifying exacerbation risk and symptom burden:

Group A Low Risk; Less Symptoms, Group B Low Risk; More Symptoms, Group C High Risk; Less Symptoms, and Group D High Risk; More Symptoms.

Two steps should be followed when using the ABCD Assessment tool. The first step is to assess patient symptoms. Several reliable questionnaires such as the Modified British Medical Research Council Questionnaire (mMRC), COPD Assessment Test (CAT), and COPD Control Questionnaire (CCQ) may be used to assess symptom burden and health status. The mMRC only assesses the impact of breathlessness on health-related quality of life. However, patients with COPD often exhibit additional symptoms such as cough, chest tightness, and mucus production. Therefore, scales that provide a more comprehensive assessment of symptoms, (e.g., CAT) may be preferred. Nevertheless, patients are considered to have a high level of symptoms when scoring ≥2 on the mMRC or ≥10 on the CAT. Of note, it is only necessary to use one of these scales when assessing symptom burden.

Table 19-5

The BODE Index Scoring System

Variable	Points			
	0	1	2	3
	≥21	<21		

Body mass index (kg/m^2)				
Obstruction of airflow (FEV$_1$% predicted)	≥65	50–64	36–49	≤35
Dyspnea?	None or only with strenuous exertion	Walking up a slight hill	Walking on the level	Getting dressed
Exercise capacity (6-minute walk distance, feet)	>1,148	820–1,149	492–819	<492

Approximate 4-year survival based on total BODE score:
  0–2 points: 80%
  3–4 points: 70%
  5–6 points: 60%
  7–10 points: 20%
BODE, body mass index, degree of airflow obstruction, dyspnea, and exercise capacity index.
Celli BR et al. The body-mass index, airflow obstruction, dyspnea, and exercise capacity index in chronic obstructive pulmonary disease. N Engl J Med. 2004;350:1005.

The second step involves an assessment of the patient's risk for future exacerbations. Patients are considered to be in the "high risk" category if the patient has experienced 2 or more exacerbations in the previous year or if the patient has had 1 exacerbation that led to a hospitalization within this time period.[1]

Although the GOLD management strategy can provide important prognostic information, other comprehensive assessment tools may too provide discriminating information with regard to survival in COPD. For example, a scoring system based on body mass index, obstruction on spirometry, dyspnea level, and exercise capacity (BODE) can predict survival in COPD better than the FEV$_1$ alone (Table 19-5).[41]

Natural Course

The natural course of COPD is highly variable, generally spanning 20 to 40 years and influenced by numerous factors, including genetic predisposition, exposure to inhaled irritants (tobacco smoke, workplace, or environmental pollutants), and repeated infections. The typical smoker who develops COPD remains asymptomatic for the first two decades of smoking, except for more frequent viral or bacterial upper respiratory tract infections. Clinical symptoms appear after significant irreversible lung damage occurs. After 25 to 30 years of smoking, mild dyspnea on exertion is commonly noted and can be accompanied by a morning cough; however, physical examination and chest radiograph are often unremarkable.[30] With continued exposure to risks (e.g., cigarette smoking), the disease progresses and patients develop increased airflow limitation and worsened dyspnea on exertion, and increased cough and sputum production. Ultimately, structural changes result in alveolar hypoxia and the secondary problems of pulmonary hypertension and cor pulmonale.

Exacerbations, or flares, of COPD are common and can be infectious or noninfectious. Moderate to severe exacerbations may require hospitalization. Acute or chronic respiratory failure can develop secondary to an acute infection, or other factors, including oversedation, heart failure, or pulmonary embolism.[42,43]

GENERAL MANAGEMENT CONSIDERATIONS

The overarching goals of COPD management involve two main principles. First, to reduce symptoms (i.e., relieve symptoms, improve exercise tolerance, and improve health status); and second, to reduce risk (i.e., prevent disease progression, prevent and treat exacerbations, and reduce mortality).[1] Unfortunately, the only interventions that have been proven to reduce mortality in COPD are smoking cessation, oxygen therapy for patients with severe hypoxemia at rest, and lung volume reduction surgery for very select patients with advanced emphysema.[11,44–46] As such, many of the interventions are aimed at alleviating symptoms and maximizing quality of life.

Because continued cigarette smoking is associated with accelerated progression of disease in susceptible smokers, smoking cessation is critical to disease treatment. Strategies for smoking cessation are detailed in Chapter 91, Tobacco Use and Dependence. The benefits of smoking cessation in COPD include decreases in respiratory symptoms, exacerbation rate, and lung function decline.[25,47] It should also be noted that cardiovascular complications, including coronary artery disease, are more common in patients with COPD and that smoking cessation may attenuate morbidity and mortality from this complication.

Immunizations provide protection against serious illness and death in patients with COPD.[48] The efficacy, benefit, and cost-effectiveness of vaccination against influenza among this population are significant.[49] In addition, the pneumococcal polysaccharide vaccine is recommended to all patients with COPD,[1] as well as, in adult patients 19 through 64 years of age who smoke cigarettes or have asthma.[50]

Pulmonary rehabilitation is an exercise-based program aimed at maximizing the patient’s functional status and quality of life. Multiple studies have now documented the beneficial effects of pulmonary rehabilitation, particularly with respect to improved exercise tolerance and alleviation of dyspnea.[51] In addition, cost-effective analysis suggests that pulmonary rehabilitation programs are very cost-effective.[52] Pulmonary rehabilitation programs are multidisciplinary programs typically running for 6 to 12 weeks, two to three sessions per week. A number of interventions are used, including breathing retraining, psychosocial counseling, education, dietary counseling, and airway clearance techniques for patients with chronic sputum production. Arm strengthening and arm endurance exercises are important because patients with COPD commonly have excessive dyspnea when using their upper extremities.[51] The most important component of a pulmonary rehabilitation program is lower extremity endurance training, often using a treadmill or bicycle ergometer. Because the large muscle groups have diminished oxidative capacity,[53–55] likely related to deconditioning and chronic inflammation,[56,57] patients with COPD convert to anaerobic metabolism at low levels of exercise. This leads to increased lactate production for a given level of activity[58] and, subsequently, increased CO_2 production. Lower extremity endurance training can significantly improve mitochondrial oxidative capacity in patients with COPD.[53,59] This physiologic benefit is believed to be an important mechanism whereby pulmonary rehabilitation exerts its effect. Other important effects, such as alleviation of depression and anxiety, may be important as well.[51]

As mentioned, patients with severe resting hypoxemia have improved mortality with supplemental oxygen treatment. Based on studies published in the 1980s, it has been found that patients with a Pao_2 of 55 mm Hg or less (corresponding to an oxygen saturation of ~88%) have decreased mortality and evidence of better end-organ function when treated with supplemental oxygen.[45,46] Whether supplemental oxygen benefits subjects with moderate hypoxemia, corresponding to an oxygen saturation of 89% to 93%, is the objective of an ongoing, randomized, multicenter study, the Long-Term Oxygen Treatment Trial (LOTT).[60]

PHARMACOTHERAPY

The fundamental goals of medication use are to prevent or control symptoms, reduce the frequency and severity of exacerbations, and improve both health status and exercise tolerance. The currently available medications used to treat COPD, however, do not alter the natural course of this condition; therefore, pharmacotherapy should be individualized for each patient and focused on symptom management to improve quality of life.[25,61–63] Because of the potential for limited benefit with therapy, a specific set of desired goals must be defined for each patient before therapy is initiated. The initial outcomes should be realistic and developed jointly by the caregiver and the patient. In general, COPD is a progressive disease, and general guidelines will apply to most patients with COPD as they begin to require pharmacologic management.

- The number of medications will cumulatively increase as the disease worsens.
- Patients will eventually require daily maintenance therapy for sustained periods unless adverse effects of the medication(s) preclude further use.
- Interindividual variability in medication response is expected and requires careful monitoring over a continuum of time to ensure an acceptable benefit-to-risk ratio is achieved.

When medications are initiated or modified, a minimal trial period of several weeks to a few months is usually recommended before determining their full benefit. Single-dose challenges and frequent alterations in therapy do not allow adequate assessment and can compromise patient adherence. No consensus currently exists on the most appropriate outcome measure or degree of improvement needed to be determined clinically significant.

Although the standard for assessing benefit from treatment has been to measure spirometric improvement in FEV_1, many patients will not demonstrate noticeable changes after either an acute or extended therapeutic trial of any therapy. Increasingly, clinicians are considering other measures to determine the benefit of therapy. These include measuring improvements in quality of life, dyspnea, and exercise tolerance.[64] Other appropriate measures may include COPD exacerbation rates and utilization of health care resources. In most patients, it is important to consider the use of multiple outcome measures, both objective and subjective, to guide the therapeutic decision-making process.

Bronchodilators

Bronchodilators are central to the symptomatic management of COPD and include short-acting and long-acting β_2-agonists, short-acting and long-acting anticholinergic agents, and theophylline. These medications, although pharmacologically distinct, improve airflow primarily by reducing bronchial airway smooth muscle tone. In COPD, the spirometric response, as measured by FEV_1, can be variable and, in many cases, will demonstrate no change, although the patient may subjectively feel better. This can be attributed to treatment facilitating emptying of the lungs and a reduction in thoracic hyperinflation at rest and during exercise. No clear evidence exists for benefit of one bronchodilator over another in the chronic management of COPD, although inhaled therapy is generally preferred over oral therapy to achieve a more rapid onset of action and to minimize the risk of systemic exposure and adverse events. Generally, the choice of treatment should be individualized based on the frequency and severity of symptoms, as well as future exacerbation risk. The GOLD Report offers a systematic approach to initiating and adjusting pharmacotherapy in patients with COPD (Table 19-6). Additional factors such as product availability, cost, patient preference, and overall clinical response should be further tailored to the patient.[1]

Short-acting β_2-agonists (e.g., albuterol) with or without a short-acting anticholinergic (e.g., ipratropium) is usually preferred for exacerbations and acute symptoms because of their more rapid onset of action and relatively short duration of activity when compared with long-acting agents.[1] A short or long acting bronchodilator should be offered to patients who have few symptoms and are at a low risk for exacerbations (Group A). As disease progresses and the frequency of symptoms increases along with medication requirement, the patient should be transitioned onto daily maintenance bronchodilator therapy.[37] At this point, substitution of a short-acting agent with a long-acting agent is recommended because the bronchodilator effect will be sustained for a longer duration, thus reducing the number of daily inhalations. This strategy will also enhance patient adherence. The side effects of bronchodilators, particularly β_2-agonists, are predictable and dose dependent, even with excessive use of inhaled agents. The most common adverse effects are an extension of stimulation of β_2-adrenergic receptors that can produce resting sinus tachycardia or provoke cardiac dysrhythmias in predisposed individuals, especially the elderly. Precipitation of somatic tremors and hypokalemia can also occur with excessive use.

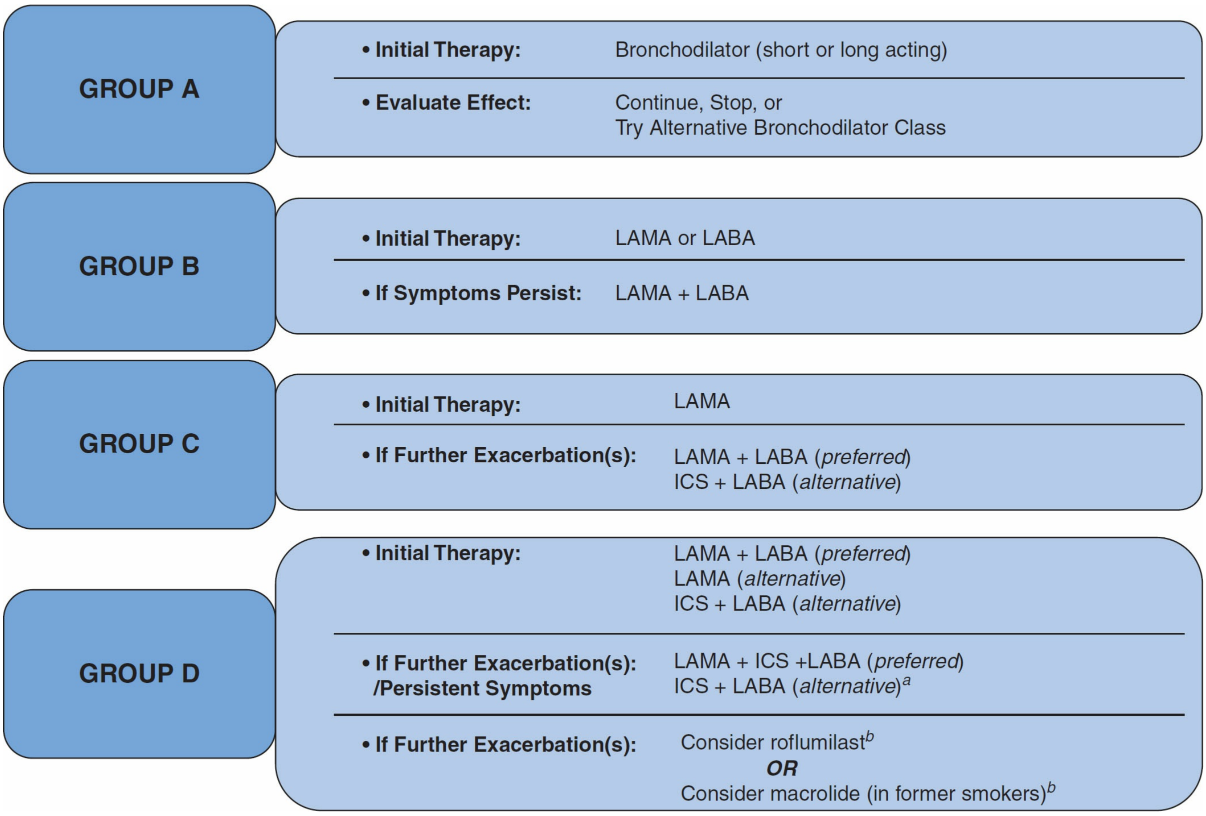
The relationship between β_2-agonist use and cardiovascular complications remains somewhat controversial. It is recognized that albuterol and long-acting inhaled β_2-sympathetic agents can induce systemic sympathetic states, hypokalemia, and other metabolic derangements that can contribute to cardiac rhythm disturbances. This has led to speculation that these abnormalities could contribute to an increase in cardiovascular death among patients with COPD using β_2-agonist inhalers.[65] Nevertheless, this speculation has been largely refuted by the TORCH (Towards a Revolution in COPD Health) study, in which more than 6,000 patients with COPD were randomly assigned to treatment with salmeterol, fluticasone, combination salmeterol–fluticasone, or placebo.[66] Overall mortality, cardiovascular mortality, and cardiovascular-related adverse events were no greater in the salmeterol group compared with any of the other groups.

Inhaled anticholinergic agents are generally well tolerated by virtue of their minimal systemic absorption. Excessive dry mouth is the most common complaint from patients who use inhaled anticholinergic agents, both short- and long-acting. It has been suggested that regular use of inhaled anticholinergic agents increases the risk of cardiovascular complications.[67,68] However, a recent large prospectively performed randomized trial found a decreased risk of cardiovascular complications among COPD patients using the long-acting anticholinergic tiotropium on a regular basis.[69]

It is not unusual to find reports in the literature that suggest superiority of one bronchodilator class versus another for COPD treatment.[70] It is difficult, however, to predict individual responses to treatment. For some patients, β_2-agonist bronchodilators will increase airflow, improve pulmonary function test results, and reduce symptoms of dyspnea.[71] Others may achieve greater improvement with an anticholinergic in comparison with a β_2-agonist.[72,73] Still others may not have a reversible component with either drug, but yet may perceive symptomatic benefit.[74,75] Thus, the therapeutic regimen should be reviewed with the patient at each follow-up visit to assess response. Careful review of adherence, technique, and response to therapy should be assessed before adjusting therapy.

Table 19-6

Therapeutic Selection by COPD Group



GROUP A	**• Initial Therapy:**	Bronchodilator (short or long acting)
	• Evaluate Effect:	Continue, Stop, or Try Alternative Bronchodilator Class
GROUP B	**• Initial Therapy:**	LAMA or LABA
	• If Symptoms Persist:	LAMA + LABA
GROUP C	**• Initial Therapy:**	LAMA
	• If Further Exacerbation(s):	LAMA + LABA (*preferred*) ICS + LABA (*alternative*)
GROUP D	**• Initial Therapy:**	LAMA + LABA (*preferred*) LAMA (*alternative*) ICS + LABA (*alternative*)
	• If Further Exacerbation(s): /Persistent Symptoms	LAMA + ICS +LABA (*preferred*) ICS + LABA (*alternative*)[a]
	• If Further Exacerbation(s):	Consider roflumilast[b] ***OR*** Consider macrolide (in former smokers)[b]

ICS = Inhaled Corticosteroid LABA = Long Acting b2-agonist LAMA= Long Acting Antimuscarinic (anticholinergic)

[a] If prior regimen consisted of LAMA monotherapy or combination long acting bronchodilator therapy

[b] Recommended "add-on" therapies Theophylline or a Short-Acting β_2 Agonist ± Short-Acting Anticholinergic may be used alone or in combination with options listed above. ICS, inhaled corticosteroid; → PDE 4 Inhibitor, phosphodiesterase 4 inhibitor.

Source: GOLD (Global Initiative for Chronic Obstructive Lung Disease). Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease. Updated 2017 [online]. Figure 4.1, p. 85. http://www.goldcopd.org Accessed July 25, 2017.

Theophylline is a methylxanthine that induces bronchodilation by relaxing the smooth muscle of the bronchi. Although not fully understood, its pharmacologic activity has been attributed to nonselective inhibition of phosphodiesterase, inhibition of extracellular adenosine (a bronchoconstrictor), stimulation of endogenous catecholamines, and antagonism of prostaglandins PGE_2 and $PGF_{2\alpha}$.[76]

Theophylline has been shown to provide greater symptomatic improvement when compared with placebo,[77] though it is considered to be less effective and usually less well tolerated than inhaled long-acting bronchodilators.[1] Theophylline may provide additional symptomatic improvement via stimulation of diaphragmatic contractility and antiinflammatory effects. However, the clinical significance of these findings remains to be determined.[1,77–79]

Currently, theophylline is reserved for patients who do not tolerate, or fail to adequately respond to, a combination of first-line bronchodilators. It is relatively inexpensive and studies showing clinical benefit have involved mostly slow-release preparations. The major limitation of theophylline is its relatively narrow therapeutic index, potential to cause significant adverse events, and requirement for blood monitoring of drug levels.[1]

Selective Phosphodiesterase 4 (PDE4) Inhibitors

In 2011, the US Food and Drug Administration (FDA) approved roflumilast (Daliresp) as an orally administered selective PDE4 enzyme inhibitor to reduce the risk of COPD exacerbations in patients with severe COPD associated with chronic bronchitis and a history of exacerbations.[80] Recent guidelines recommend the use of roflumilast in patients who are not adequately controlled by long-acting bronchodilators and continue to experience frequent exacerbations. It has been recommended to use this agent in combination with at least one long-acting bronchodilator.[1] Although roflumilast has been shown to improve FEV_1 by 40 to 60 mL compared to placebo, it is not a bronchodilator and is not indicated to relieve acute bronchospasm.[80,81] In comparison with theophylline, roflumilast has much less potential for drug–drug interactions and does not require drug level monitoring. Though it is metabolized to an active metabolite via CYP3A4 and CYP1A2 pathways, it be used with caution in patients receiving strong inducers or inhibitors of these enzymes and should be avoided in those with significant hepatic impairment. Significant adverse effects, including diarrhea, nausea, weight loss (~2 kg), and adverse psychiatric effects such as anxiety and depression have been reported.[1,80,81]

Corticosteroids

Historically, initiation of a short (2-week) course of oral corticosteroids was often advocated to identify patients with COPD who might benefit from long-term treatment. Recent evidence, however, indicates that a short-course challenge is a poor method to predict patients who will benefit from long-term ICS use.[63,82] Given the lack of evidence and risk for significant side effects that include steroid myopathy and loss of bone density, chronic systemic corticosteroid therapy is not generally recommended. For patients with COPD experiencing an acute exacerbation of their disease, the short-term use of systemic corticosteroids has proven efficacy.[83]

In contrast, inhalation of corticosteroids leads to substantially less systemic absorption, thereby minimizing many of the risks associated with systemic corticosteroid therapy. On the basis of this, several national and international studies have been conducted to evaluate the potential benefit of ICS maintenance therapy.[61–63,84] Well-conducted clinical trials have revealed that daily treatment with ICS does not delay the long-term decline in FEV_1 in patients with COPD. Daily use can result, however, in a reduction in the frequency of exacerbations and an improvement in overall health status, particularly in patients with more advanced disease.[85–88] The TORCH investigation demonstrated that ICS use in combination with a long-acting β_2-agonist is more effective than either agent alone or placebo in patients with advanced COPD.[66] Specifically, patients using combination therapy (one inhalation twice daily) experienced decreased exacerbations, improved spirometric values, and increased health status. Although no difference was seen in mortality or disease progression among treatment groups, some guidelines recommend ICS as a treatment option in symptomatic patients with COPD and an FEV_1 less than 60% predicted.[1,89] Most trials to date involving ICS have studied patients on moderate to high doses. Common adverse effects include oral candidiasis, dysphonia, and skin bruising. ICS either alone or in combination with a bronchodilator may increase the risk of pneumonia in some patients. However, risk estimates have varied due to inconsistencies related to how pneumonia is defined, reported, and diagnosed among trials.[90] Additionally, withdrawal from ICS therapy has led to exacerbations in some patients, but a more recent study found no increases in exacerbation risk among patients with moderate to severe COPD when the ICS dose was tapered over a 3-month period.[1,91] Given the paucity of data, patient symptoms and lung function should be monitored when stepping down therapy.

Triple therapy involving a long-acting β agonist and a long-acting anticholinergic with an ICS may further improve lung function, quality of life, and reduce exacerbations, but further study is needed.[92,93]

PHARMACOLOGIC THERAPY BY DISEASE SEVERITY

As described, it is expected that patients with COPD will require an increase in the dose and number of medications to effectively manage their disease with time. Patients with infrequent or intermittent symptoms who are at a low risk for a future

COPD exacerbation (Group A) should be offered either a short or long acting bronchodilator. As the disease progresses and patients become more symptomatic, as-needed use of bronchodilators alone will not maintain adequate relief from these symptoms. Long-acting bronchodilators have been shown to be more effective and convenient for patients experiencing more persistent symptoms (Group B). These patients may also continue to use a short-acting bronchodilator as needed for additional symptomatic relief. The addition of an ICS may be recommended in patients who are classified as having a "high risk" for a future exacerbation (Group C or Group D).[1] Patients who have a history or underlying findings consistent with an asthma component (e.g., Asthma COPD Overlap Syndrome) or those with elevated eosinophil counts may be most likely to benefit, although further study is needed.

In general, nebulization of bronchodilators is primarily reserved for the acute-care setting for quick symptomatic relief and is not advocated routinely for home use. In select patients who are not achieving maximal benefit with standard inhalation delivery devices, a 2-week trial with nebulized therapy can be considered and then continued if a clear benefit is observed.[94]

COPD EXACERBATION

An exacerbation of COPD is defined as "an acute worsening of respiratory symptoms that results in additional therapy.[1] Acute exacerbations of COPD are important events in the natural history of this disease.[95,96] They are associated with considerable morbidity; severe exacerbations are associated with an increased mortality.[96] Furthermore, acute exacerbations are responsible for a high percentage of the health care costs associated with COPD.[1,5]

The cause of acute exacerbations is believed to be a result of respiratory tract infections, either viral or bacterial, air pollution, or other environmental exposures.[97,98] These triggers can initiate increased bronchospasm and airway resistance in an individual with already compromised lung function. Although mild exacerbations may be readily managed with outpatient therapy, severe exacerbations can result in respiratory failure and death, particularly if they occur in a patient with severe COPD.

Key therapeutic interventions for acute COPD exacerbations include regular bronchodilator therapy, a short course of systemic corticosteroid therapy, antibiotics, and supportive measures such as oxygen therapy. Bronchodilator therapy consisting of a short-acting β_2-agonist with or without a short-acting anticholinergic is given as needed by MDI or nebulizer every 3 to 4 hours.

For videos that show proper use of many types of inhalers, go to **http://use-inhalers.com/ or http://www.nationaljewish.org/healthinfo/multimedia/asthma-inhalers.aspx**. For a video of how to use a nebulizer, go to **http://www.nationaljewish.org/healthinfo/medications/lung-**

diseases/devices/nebulizers/instructions.aspx.

Systemic corticosteroids shorten recovery time, improve lung function and hypoxemia when added to other treatments used to manage exacerbations. Although there are insufficient data to support the optimal duration of treatment, a 5-day course of prednisone has been shown as effective as a 14-day course for reducing the occurrence of a re-exacerbation within a 6-month follow-up period.[83] A prolonged 10-day course of prednisone 30 to 40 mg per day may be a reasonable option for some patients.[30,99] High-dose intravenous corticosteroids (methylprednisolone 125 mg every 6 hours) have been shown to be effective in hospitalized patients.[100] Such large doses, however, are associated with an increased risk of hyperglycemia, and it is not known whether this regimen is superior to lower dose oral regimens. A recent pharmacoepidemiologic study involving nearly 80,000 patients hospitalized for acute COPD exacerbations found no difference in treatment failure in patients receiving intravenous corticosteroids compared with those taking lower dosages of oral corticosteroids.[101]

Decisions about antibiotic use in the setting of an acute exacerbation should be made based on the presence of the following respiratory symptoms: increased dyspnea, sputum volume, and sputum purulence. Data suggest that if two of the three are increased, antibiotics are beneficial.[102] The optimal antibiotic regimen for acute COPD exacerbations has not been rigorously studied. For many outpatients, however, generic, low-cost antibiotics, including amoxicillin, trimethoprim–sulfamethoxazole, or doxycycline, may be very effective. Indeed, these agents can effectively cover the most common bacterial causes of acute exacerbations, including Streptococcus pneumoniae, Haemophilus influenzae, and Moraxella catarrhalis. Guidelines suggest that hospitalized patients in respiratory failure should receive broad-spectrum antimicrobials that include activity against Pseudomonas aeruginosa, because these patients have a higher risk for more resistant organisms.[30]

COPD GROUP A (LOW RISK; LESS SYMPTOMS)

Diagnosis

CASE 19-1

QUESTION 1: T.A., a 51-year-old white male smoker, presents with daily cough and mild dyspnea on exertion with strenuous activity. He has noticed that walking up two flights of steps bothers him, when previously it did not. He has had a slight amount of wheezing, but no chest pain. He has no known chronic medical problems. He has smoked 1.5 packs/day for 34 years and he continues to smoke that amount. His physical examination is unremarkable. COPD is suspected. What diagnostic test should be ordered?

A clinical diagnosis of COPD should be considered in any patient presenting with persistent dyspnea, chronic cough, or sputum production with a history of exposure to risk factors such as cigarette smoking. Spirometry is the gold standard diagnostic test and should be considered to confirm the diagnosis of COPD. The main values gleaned from spirometry will include the FVC, FEV_1, and the FEV_1/FVC ratio. An FEV_1/FVC ratio of less than 0.70 following a bronchodilator indicates obstruction to expiratory flow consistent with COPD. The FEV_1 can be used in conjunction with other clinical indicators to further determine disease severity.

CASE 19-1, QUESTION 2: Office spirometry demonstrates an FEV_1/FVC of 0.69 and an absolute FEV_1 of 81% of predicted. T.A. has a CAT score of 7 and has had one exacerbation in the past year, which was managed at home. Using GOLD criteria, which COPD risk group should T.A. be assigned and what other diagnostic tests would be necessary before initiating therapy?

Based on GOLD guidelines, this patient has clinical features most consistent with "Group A." A CXR study is often performed to exclude other respiratory diagnoses contributing to the patient's symptoms; however, the abnormal spirometry is sufficient to make the diagnosis of COPD and to initiate therapy.

In certain cases of diagnostic uncertainty or in patients with severe disease being considered for surgical intervention, such as lung volume reduction surgery, a complete set of pulmonary function tests, including the determination of lung volumes and DLCO, may be performed. Complete pulmonary function testing, however, is not necessary to make the diagnosis of COPD.

In patients with more severe symptoms or airflow obstruction, assessment of oxygen status by means of pulse oximetry or ABG may be necessary. Pulse oximetry should be used to assess stable patients if the FEV_1 is <35% of predicted or with clinical signs suggestive of respiratory failure or right heart failure. ABGs are recommended if peripheral saturation is <92%.[1] An α_1-antitrypsin level to rule out α_1-antitrypsin deficiency is generally reserved for patients with disease onset at a young age (<45 years of age), or in patients with a strong family history of COPD.[1]

Therapeutic Management

CASE 19-1, QUESTION 3: What therapeutic interventions should be recommended for T.A. at this point?

SMOKING CESSATION

A comprehensive smoking cessation plan with therapy should be initiated for T.A. because smoking cessation is the only intervention proven to decrease the decline in FEV_1 associated with COPD.[1,25] Although pharmacologic interventions for smoking cessation are covered elsewhere in the text (see Chapter 91, Tobacco Use and

Dependence), it should be noted that a personalized message may be beneficial for this patient. Indeed, discussion of spirometry results with the patient can provide an important opportunity to deliver a personalized message.[103] It can be explained to T.A. that he is beginning to develop definite irreversible abnormalities in his pulmonary function and, therefore, is a "susceptible" smoker. It is critical for him to stop smoking and thereby prevent continued deterioration in lung function.

IMMUNIZATIONS

In addition to smoking cessation, this patient's immunization status should be evaluated.[104] According to the GOLD guidelines and in the absence of contraindications, T.A. is a candidate for vaccination against influenza and pneumococcal pneumonia, even though he is in the early stages of COPD.[1] Patients with COPD are at risk for increased morbidity and mortality if they develop either of these infectious complications.

Individuals at greatest risk for significant morbidity and mortality from influenza and pneumonia are those with chronic disease, including lung disease. Optimally, the influenza vaccine should be administered during the fall before the end of October.[105] This allows an adequate antibody response before the peak influenza season, which typically occurs within the first quarter of the year. Annual immunization is required to ensure adequate antibody protection against influenza virus and is effective in reducing morbidity and mortality from influenza.[106]

The pneumococcal polysaccharide vaccine (Pneumovax 23, PPSV23) is also recommended for patients with COPD.[1] The PPSV23 contains 23 S. pneumoniae serotypes and provides protection against S. pneumoniae.[107] The Advisory Committee on Immunization Practices (ACIP) now recommends a one-time dose of the PCV13 in addition to the PPSV23 in patients ≥65 years of age. These vaccines should be separated as indicated to ensure an optimal immune response.[108] To manage T.A.'s symptoms, treatment with an as-needed bronchodilator may be reasonable to start. Bronchodilators are the primary pharmacologic therapy used in the management of COPD.[1,30]

Available bronchodilator therapies include short or long acting β^2-agonists, short or long acting anticholinergics and methylxanthines (theophylline). For initial treatment, the most common choice for T.A. would be a short-acting, inhaled β_2-agonist, (e.g., albuterol), a short-acting inhaled anticholinergic (e.g., ipratropium), or a combination of these two agents. Either of these therapies has a relatively short onset of action and is effective in relieving symptoms. Table 19-7 summarizes inhaled therapeutic options for COPD.

SHORT-ACTING β_2-AGONISTS

β_2-Agonists produce bronchodilation by relaxing bronchial smooth muscle through activation of cyclic adenosine monophosphate (cAMP).[109] The inhalation route of delivery for bronchodilators is recommended over oral therapy based on safety and efficacy. The dose–response curve among all available bronchodilators is relatively flat and similar. No evidence suggests that one agent is superior to another.

Albuterol is the most frequently used agent in this class. It is available as an MDI or DPI 90 mcg/inhalation. It is also available as a premixed solution for nebulization (e.g., adult dose 2.5 mg/0.5 mL), as well as a concentrated solution 5 mg/mL (0.5%) that requires saline to be prescribed separately. The onset of action of short-acting β_2-agonists (e.g., albuterol, levalbuterol) is rapid (within 5 minutes) and generally reaches maximal effect in 15 to 30 minutes. The duration of action is approximately 4 hours. Although inhaled β_2-agonists are usually well tolerated, some patients experience adverse effects (tremors, tachycardia, or nervousness) with even low dosages. Although concern has been expressed about the safety of short-acting, inhaled β_2-agonists in patients with cardiac disease, a cohort study using the Saskatchewan Health Services database concluded that there was no increased risk for fatal or nonfatal myocardial infarction in patients using these agents.[110]

Table 19-7

Inhaled Therapeutic Options for COPD

Medication Brand Name and Strength (per inhalation)	Chemical Name	Device	No. of Doses[a]/Device or Box
Short-Acting β_2 Agonists			
ProAir HFA 90 mcg, Proventil HFA 90 mcg, Ventolin HFA 90 mcg	Albuterol	MDI	200[b]
ProAir, RespiClick 90 mcg AccuNeb 0.63 mg/3 mL, 1.25 mg/3 mL	Albuterol	DPI	200
Proventil 2.5 mg/3 mL (0.083%), [d]5 mg/mL (0.5%) concentrate	Albuterol	Nebulizer	Varies
Xopenex HFA 45 mcg	Levalbuterol	MDI	200[b]
Xopenex 0.31 mg/3 mL, 0.63 mg/3 mL, 1.25mg/3 mL,[d]1.25 mg/0.5 mL concentrate	Levalbuterol	Nebulizer	Varies
Short-Acting Anticholinergic			
Atrovent HFA 17 mcg	Ipratropium	MDI	200[b]
Atrovent 0.02% (0.5 mg/2.5 mL) vial	Ipratropium	Nebulizer	25ct, 30ct, 60ct
Short-Acting Anticholinergic + β_2 Agonist Combination			
Combivent Respimat 20–100 mcg	Ipratropium + Albuterol	SMI	120[b]

DuoNeb 0.5–2.5 mg/3 mL vial	Ipratropium + Albuterol	Nebulizer	30ct, 60ct
Long-Acting β_2 Agonists			
Serevent Diskus 50 mcg	Salmeterol	DPI	60
Foradil Aerolizer 12 mcg	Formoterol	DPI	60 blister units
Brovana 15 mcg/2 mL vial	Arformoterol	Nebulizer	30ct, 60ct
Perforomist 20 mcg/2 mL vial	Formoterol	Nebulizer	30ct, 60ct
Long-Acting β_2 Agonists (Once Daily)			
Arcapta Neohaler 75 mcg	Indacaterol maleate	DPI	30 blister units
Striverdi Respimat 2.5 mcg	Olodaterol	SMI	60[b]
Long-Acting Anticholinergics			
Spiriva HandiHaler 18 mcg	Tiotropium	DPI	30 blister units
Spiriva Respimat 2.5 mcg	Tiotropium	SMI	60[b]
Tudorza Pressair 400 mcg	Aclidinium bromide	DPI	60
Incruse Ellipta 62.5 mcg	Umeclidinium	DPI	30 blister units
Seebri Neohaler 15.6 mcg	Glycopyrrolate	DPI	60 blister units
Inhaled Corticosteroid + Long-Acting β_2 Agonist Combination			
[c]Advair Diskus 250/50 mcg	Fluticasone + Salmeterol	DPI	60
[c]Symbicort HFA 160 mcg/4.5 mcg	Budesonide + Formoterol	MDI	120[b]
[c]Breo Ellipta 100–25 mcg	Fluticasone + Vilanterol	DPI	60 blister units
Long-Acting Anticholinergic + β_2 Agonist Combination			
Anoro Ellipta 62.5–25 mcg	Umeclidinium + Vilanterol	DPI	60 blister units
Stiolto Respimat 2.5–2.5 mcg	Tiotropium + Olodaterol	SMI	60[b]
Utibron Neohaler 15.6–27.5 mcg	Glycopyrrolate + Indacaterol	DPI	60 blister units
Bevespi Aerosphere 9–4.8 mcg	Glycopyrrolate + Formoterol	MDI	120[b]

[a] Institutional sizes not included.

[b] Number of doses after initial priming.

[c] Only FDA-approved strength for COPD other strengths may be commercially available.

[d] Nebulized solutions marked “0.5 mL concentrate” should be diluted with 0.9% sodium chloride solution.

DPI, dry-powder inhaler; MDI, metered-dose inhaler; SMI, soft mist inhaler.

SHORT-ACTING ANTICHOLINERGICS

The parasympathetic (cholinergic) nervous system plays a primary role in the control of bronchomotor tone in COPD. By inhibiting cyclic guanosine monophosphate (cGMP) in the lung, aerosolized anticholinergic drugs are effective bronchodilators. The bronchodilation produced by anticholinergics in patients with stable COPD has been shown to be non-inferior to that achieved by inhaled β_2-agonists.

Ipratropium bromide is the primary short-acting anticholinergic agent used in COPD. It is marketed as both an MDI (17 mcg ipratropium per puff) and as a solution for nebulization (0.5 mg ipratropium/2.5 mL). Ipratropium has an average onset of effect within 15 minutes, with a maximal bronchodilator effect in 60 to 90 minutes, although some patients may experience more rapid symptom relief. The duration of action is approximately 6 hours. Although some reports suggest a quicker onset of action, patients should be advised that the relief of acute symptoms will be slower compared with an inhaled β_2-agonist. A typical dose of ipratropium is two inhalations four times daily.[111] Although well tolerated, some patients experience dry mouth, nausea, and blurred vision with use of ipratropium.

The anticholinergic actions of ipratropium are localized predominantly in the lungs, with an apparent specificity of action in the larger airways. Because it has minimal effects on sputum viscosity, there is little problem with drying of airway secretions. In addition, ipratropium's structure as a quaternary amine increases its polarity, thereby minimizing absorption from the lung and systemic side effects. These structural properties also reduce penetration across the blood–brain barrier, reducing the incidence of confusion and other central nervous system (CNS) side effects.

COMBINATION β^2-AGONISTS–ANTICHOLINERGICS

Combination therapy with two different classes of bronchodilators is appealing because it may decrease the cumulative dose of individual agents, thereby decreasing the risk of side effects while maintaining the benefits of each medication. In addition, anticholinergics and β-agonists have different mechanisms of action, and combining the two classes may provide additional benefit. Indeed, it has been demonstrated that combination therapy results in significantly greater increases in FEV_1 compared with use of either albuterol or ipratropium alone.[112] The Combivent Respimat contains both albuterol and ipratropium in a single inhaler.[113] The respimat is a novel propellant-free inhalation device that produces a slow moving mist from mechanical energy produced by the release of a compressed spring.

Umeclidinium plus vilanterol (Anoro Ellipta), and tiotropium plus olodaterol (Stiolto Respimat), are once-daily products that combine a long-acting anticholinergic plus a long-acting β_2-agonist in a single device.[114,115] Glycopyrrolate is available in combination with indacaterol (Utibron™ Neohaler) and in combination with formoterol (Bevespi® Aerosphere), but both dosed twice daily.[116,117] Each has been approved for the maintenance treatment of airflow obstruction in patients with COPD.[114–117]

COPD GROUP B (LOW RISK; MORE SYMPTOMS) WITH DISEASE PROGRESSION

Therapeutic Management

CASE 19-2

QUESTION 1: J.O., a 46-year-old woman with a 32-pack-year history of cigarette smoking, presents with increasing shortness of breath. She gets winded walking on level ground after about 100 yards. She quit smoking 2 years ago. The chronic cough that she previously had lessened after smoking cessation, but the dyspnea is now somewhat worse, despite use of an albuterol inhaler on an as-needed basis. On examination, mild wheezing is noted. A CXR is unremarkable. Office spirometry demonstrates an FEV_1/FVC ratio of 0.64 and an absolute FEV_1 of 2.0 L or 60% of predicted. J.O. has a CAT score of 20, and has had one exacerbation in the past year, which was managed at home. Post-bronchodilator treatment demonstrated an FEV_1 increase of 100 mL, a 5% increase. How should J.O. be treated?

J.O. would be considered to be in Group B. She has had progression of dyspnea despite smoking cessation and the addition of a short-acting β_2-agonist.She is still at a low risk for an exacerbation based on her exacerbation history. Because pharmacologic management of COPD involves a stepwise approach, regular use of a long-acting bronchodilator would be the next step in treatment.

The main classes of long-acting bronchodilators currently available include β_2-agonists and anticholinergics. Both classes can be further divided into two groups according to duration of activity—those producing bronchodilation for 12+ hours and those producing bronchodilation for 24+ hours. Both classes have been shown to improve quality of life and reduce dyspnea in patients with COPD.

LONG-ACTING β_2-AGONISTS

The role of inhaled, long-acting β_2-agonists in the chronic management of COPD has become well established in recent years. Available evidence with both salmeterol and formoterol shows improved pulmonary function, reduced dyspnea, and enhanced quality of life in patients with COPD.[30] Indacaterol, olodaterol, and vilanterol are dosed once daily and have a rapid onset of activity (e.g., >5 minutes) and produce bronchodilation for 24 hours or more. Their long duration of activity and comparable safety profile may offer an added convenience to some patients. A plateau in bronchodilation is achieved for most patients at the recommended dose for each agent, so no benefits exist in exceeding the recommended dose. In addition, higher doses will increase the risk of adverse events associated with β_2-agonist excess. Therefore, salmeterol should be prescribed as 42 mcg (50 mcg in a dry-powder device) twice daily and formoterol at 12 mcg twice daily.

LONG-ACTING ANTICHOLINERGICS

Vagal cholinergic tone is a reversible component of the airway limitation in COPD. Stimulation of the vagal parasympathetic nerves causes the release of acetylcholine, which then binds to muscarinic receptors to produce bronchoconstriction and secretion of mucus. Three muscarinic subtypes have been identified in human airways: the M_1, M_2, and M_3 receptors. Tiotropium is a long-acting anticholinergic that binds to the M_1, M_2, and M_3 muscarinic receptors of bronchial smooth muscle.[118] Although tiotropium dissociates rapidly from the M_2 receptor, it dissociates much more slowly from the M_1 and M_3 receptors. In fact, its dissociation from the M_1 and M_3 receptors is 100 times slower than that of ipratropium. M_1 receptors are located on parasympathetic ganglia, where they facilitate postganglionic

---

transmission, thus enhancing cholinergic tone. M_3 receptors are found on airway smooth muscle and mucous glands, where activation leads to bronchoconstriction and mucus secretion. Conversely, M_2 receptors are located on postganglionic nerve endings, where they serve as autoreceptors regulating acetylcholine release and, thereby, cholinergic tone. Thus, anticholinergics, by virtue of antagonizing M_1 and M_3 receptors, relax airway smooth muscle, and can reduce mucus secretion. M_2 blockade, however, augments acetylcholine release and thus enhances cholinergic tone. Therefore, the slower dissociation rate from both the M_1 and M_3 receptors enhances bronchodilation and allows the convenience of once-daily dosing.

Tiotropium has a very long duration of action and can provide effective bronchodilation with once-daily dosing. Numerous studies have documented its beneficial effect on pulmonary function and quality of life. The UPLIFT (Understanding Potential Long-Term Impacts on Function with Tiotropium) compared 4 years of therapy with either tiotropium or placebo in nearly 6,000 patients with COPD. Tiotropium was associated with improvements in lung function, quality of life, and exacerbation risk, but did not impact the rate of decline of FEV_1 or mortality.[69] Tiotropium is also a quaternary amine with limited systemic absorption; therefore, the agent is well tolerated, with dry mouth being the major side effect. Concerns have been raised, however, about tiotropium's safety. In particular, disparate sources have identified stroke, cardiovascular events, and death as possible adverse outcomes. After completion of UPLIFT, which included 17,721 patient-years of drug exposure, the FDA recently concluded that the appropriate use of tiotropium in COPD patients does not place them at increased risk for stroke or adverse cardiovascular events.[119] In September 2014, tiotropium was also approved to be delivered via the Respimat device. The Tiotropium Safety and Performance in Respimat (TIOSPIR) Trial is the largest COPD trial to date involving more than 17,000 patients. This trial was designed to directly compare the safety of tiotropium respimat to tiotropium delivered via the HandiHaler device. The length of time to first COPD exacerbation was also followed to compare efficacy. Both the Respimat and HandiHaler were found to have comparable results for exacerbation frequency, as well as exacerbations associated with hospitalization. The incidence of adverse events was also similar between all treatment groups.[120]

Aclidinium bromide (Tudorza PressAir), umeclidinium bromide (Incruse Ellipta), and glycopyrrolate (Seebri Neohaler) are long-acting anticholinergics recently approved for the long-term maintenance treatment of COPD. These agents have been shown to improve lung function and appear to be well tolerated.[121–123]

J.O. should be started on a long-acting bronchodilator, such as salmeterol, formoterol, or tiotropium. Once-daily β agonists such as indacaterol or olodaterol are additional options to consider. Recently approved anticholinergics such as aclidinium bromide, glycopyrrolate, or umeclidinium bromide are other potential options. It should be noted that the tolerability and efficacy of the available long-acting bronchodilators are comparable. The choice of agent is largely based on considerations such as the frequency of drug administration, the patient's ability to use the inhalation device correctly, and any out-of-pocket costs incurred by the patient. J.O. should also be instructed to continue her albuterol two puffs every 4 hours as needed. A 3-month follow-up visit should be scheduled to assess her response.

CASE 19-2, QUESTION 2: J.O. is started on tiotropium Respimat, inhale 5 mcg daily and returns to the office for a check-up in 3 months as recommended. She has had significant benefit from the medication and has had decreased wheezing and a noticeable improvement in her exercise tolerance. She asks to have spirometry repeated to see whether her lung function has improved on the new medication. Spirometry is repeated, and no significant improvement is noted in her FEV_1. She asks how she can feel better, with improved exercise tolerance, without an improvement in her lung function.

Increasing evidence suggests that bronchodilators, including long-acting β_2-agonists and anticholinergics, may reduce exercise-related dyspnea in patients with COPD by decreasing dynamic hyperinflation.[124] This improvement may be independent of marked changes in spirometry performed at rest. Indeed, because of flow limitation, these patients who exercise can have significant worsening of air-trapping, which can worsen lung compliance and adversely affect respiratory muscle mechanics. A number of studies have shown that alleviation of such dynamic hyperinflation may be an important mechanism whereby bronchodilators improve exercise tolerance in patients with obstructive lung disease.[124]

CASE 19-2, QUESTION 3: J.O. seemed to do reasonably well for a number of years, but now, 3 years later, she has noticed progressive dyspnea on exertion. She is now having difficulty carrying laundry up from her basement, and she has noticed that her overall activity level has been curtailed. Repeat office spirometry now shows an FEV_1/FVC ratio of 0.49 and an absolute FEV_1 of 49% of predicted. She now has a CAT score of

22, and has had two exacerbations in the past year. J.O. has been adherent with her tiotropium regimen and has had no other significant changes to her medical history. She remains smoke free and is not exposed to second-hand smoke in her home and work environments. What therapeutic intervention(s) should be considered at this point?

INHALED CORTICOSTEROID THERAPY

J.O has had significant deterioration in status and repeated COPD exacerbations despite appropriate adherence to tiotropium. Patients with findings consistent with COPD risk Group D should be prescribed combination therapy consisting of either an ICS + LABA or LAMA + LABA. Fixed dose combination products are preferred and several options are commercially available. (Table 19-6.) LAMA + LABA therapy may be preferred given the lower incidence of pneumonia and adverse effects related to inhaled corticosteroids.[1] One LAMA + LABA combination was superior to ICS + LABA in preventing exacerbations, and other patient reported outcomes in those with a history of prior exacerbations.[125] However, a number of multicenter, randomized, controlled clinical trials have demonstrated the efficacy of ICS in COPD.[85–88] The data have supported the use of ICS in advanced COPD and in patients with frequent exacerbations. Regular use of ICS can decrease the frequency of acute exacerbations and improve health-related quality of life in patients with an FEV_1 <60% predicted.[1]

The TORCH study has defined the benefits and potential side effects of ICS in a broader patient population of COPD.[66] In this multicenter, randomized, placebo-controlled study, mean FEV_1 was 50% predicted, but entry criteria did not require a history of repeated exacerbations. More than 6,000 patients were randomly assigned to either an ICS (fluticasone 500 mcg BID), inhaled salmeterol (50 mcg BID), combination fluticasone 500 mcg and salmeterol 50 mcg BID, or placebo. Subjects were assessed for approximately 3 years. A significant benefit was seen as measured by decreased exacerbation rates in subjects taking either inhaled fluticasone or a combination of fluticasone–salmeterol therapy. Also, an improvement was found in mortality with combination therapy that approached, but did not reach statistical significance. Overall adverse side effects with ICS were similar to those with placebo. An increased risk, however, was seen for lower respiratory tract infections with inhaled fluticasone or fluticasone–salmeterol. Of note, patients did not experience an increased risk of ocular manifestations or decreased bone density with ICS treatment.

J.O. is already taking tiotropium, so a decision must be made regarding step-up therapy. A LAMA+LABA is the preferred regimen

---

for this patient given findings consistent with COPD Group D. Tiotropium should be replaced with tiotropium + olodaterol fixed dose combination product. J.O. is already familiar with the Respimat device, which may help maintain adherence. However, other long acting bronchodilator combination products exist. A number of other potential interventions may be considered. One option would be to discontinue the tiotropium and initiate a combination ICS–long-acting β_2-agonist. Alternatively, an ICS–long-acting β_2-agonist product may be added to the tiotropium given the severity of her disease.[1,92,93] Lastly, an ICS could be added to the tiotropium, although less evidence is available to support this option.[1] Any of these choices is reasonable provided no other major contraindications in doing so exist. It should be noted that currently several corticosteroid–long-acting β_2-agonist inhalers are indicated for COPD, including Advair (fluticasone–salmeterol), Symbicort (budesonide–formoterol), and Breo Ellipta (fluticasone–vilanterol). No convincing data suggest that one preparation is superior to the other in the treatment of COPD.

The exact duration of treatment that ICS should be given before making an assessment of their benefit is not clear. Generally, an adequate trial is at least 4 to 6 weeks. One rationale for the use of ICS in COPD is, however, the prevention of acute exacerbations. As such, it can be very difficult to measure objectively the clinical benefit of the medication in individual patients.

SAFETY OF LONG-ACTING BRONCHODILATORS

CASE 19-2, QUESTION 4: J.O. calls the next day, having read something on the internet regarding possible increased risk of death in people with obstructive lung disease who take long-acting bronchodilators. She is reluctant to take it. What should you tell her?

Although some evidence in asthma indicates that use of long-acting bronchodilators may be associated with an increased risk of death, such evidence does not exist in patients with COPD. In fact, the TORCH study demonstrated no increased risk of death or adverse events among patients prescribed salmeterol compared with placebo.[66] The patient should be reassured that long-acting bronchodilators are safe in COPD.

PULMONARY REHABILITATION

CASE 19-2, QUESTION 5: J.O. also wonders whether anything else other than her medication can be done for her. What advice might be given?

At this point, pulmonary rehabilitation should be strongly considered. In fact, a comprehensive multidisciplinary pulmonary rehabilitation program should be considered in any patient with COPD experiencing persistent shortness of breath despite pharmacologic management.[51]

Increasing evidence points to COPD as a systemic process,[126] and pulmonary rehabilitation addresses the systemic nature of the disease. Although the proximate cause of disability involves the respiratory system, leading to dyspnea on exertion, this in turn has systemic consequences. Although the changes may be fairly subtle to start with, most patients will gradually manifest increasing limitations in their activity. This results in substantial deconditioning. It is likely that this deconditioning, in addition to other factors such as systemic inflammation, adversely affect skeletal muscle function. Indeed, evidence is clear that oxidative capacity is diminished in patients with COPD,[53–55] which results in overall decreased aerobic capacity and results in increased lactic acid production for a given level of activity.[56] The increased acid load will lead to a greater requirement for ventilation, which makes dyspnea more severe. The more dyspneic the patient is, the less activity he or she will do, leading to more deconditioning and recapitulation of the downward spiral.

Pulmonary rehabilitation is an exercise-based, multidisciplinary program that seeks to address this cycle.[51] Most programs generally last 8 to 12 weeks and involve two to three sessions per week. Education, particularly about medication use, as well as psychosocial counseling and breathing retraining are important components of the program. An important component of breathing retraining involves coaching patients how to use pursed lip breathing effectively. Pursed lip breathing involves pursing the lips together (as in whistling) during exhalation. This helps to slow down respirations and also provides a back-pressure in the small airways, preventing dynamic airway collapse and exercise-induced hyperinflation. The major intervention, however, is exercise training, especially endurance training of the lower extremities (e.g., using a treadmill or bicycle ergometer). Numerous studies have demonstrated that a rehabilitation program can significantly improve exercise capacity and quality of life, as well as decrease health care utilization.[51] This may partly be related to the beneficial effects of exercise on the oxidative capacity of the skeletal muscles.

J.O. should be referred to a local outpatient pulmonary rehabilitation program. A typical program involves 2-hour sessions, three times per week for 10 weeks. The sessions will involve education, breathing retraining, and strength and endurance exercise training.

COPD GROUP C (HIGH RISK; LESS SYMPTOMS)

Acute Exacerbation of COPD

ANTIMICROBIAL THERAPY

CASE 19-3

QUESTION 1: R.L., a 66-year-old man with diabetes mellitus and severe (Group C) COPD, presents with increased cough with productive discolored sputum after a “cold.” He had been hospitalized 6 weeks earlier with community-acquired pneumonia. He is a former smoker (quit 10 years ago); his current medications include tiotropium respimat 5mcg once daily, albuterol MDI two puffs every 4 hours as needed, and theophylline 200 mg BID. He also has increased dyspnea and chest tightness. On examination, he is in no acute distress and vital signs are stable. There is increased wheezing on chest examination, and the rest of the examination is unchanged. Room air pulse oximetry is 90%, and a CXR in the office shows no infiltrates. How should this patient be treated?

This patient has increased sputum purulence and increased dyspnea consistent with an exacerbation of COPD. It is not uncommon for such an exacerbation to be triggered by an upper respiratory viral infection. Given that the patient has increased dyspnea and purulent sputum production, a course of systemic corticosteroids (e.g., 40 mg of prednisone daily for 5 days) and a course of antibiotics is warranted. In outpatients with low risk factors, a low-cost antibiotic regimen is a reasonable option. Empirical treatment with an aminopenicillin with or without clavulanic acid, a macrolide, or tetracycline derivative such a doxycycline may be used.[1] Although other antibiotics are commonly given, no data support that they are superior in this setting when compared with these conventional, less-expensive agents. An acute exacerbation of COPD is one of the few instances in which antibiotic therapy is warranted to treat a respiratory infection in the absence of evidence of lower respiratory tract involvement (i.e., pneumonia).

Patients with COPD and risk factors for poor outcome (severe COPD, comorbid conditions, history of frequent exacerbations) may be more susceptible to resistant pathogens. As such, guidelines recommend that a broad-spectrum antibiotic regimen be considered, including β-lactam–β-lactamase inhibitor combinations, quinolone antibiotics, or second- or third-generation cephalosporins.[1,30]

Because of his recent hospitalization, R.L. is at increased risk for resistant pathogens, including *P. aeruginosa*. He also presents with increased sputum purulence and increased dyspnea, so a broad-spectrum antimicrobial regimen, such as oral ciprofloxacin 750 mg BID or oral levofloxacin 500 mg every day for 5 to 10 days would be appropriate. A course of oral prednisone 40 mg daily for 5 days is also indicated to improve R.L.'s lung function, reduce his hypoxemia, and hasten his recovery time.

CASE 19-3, QUESTION 2: R.L. was treated with oral ciprofloxacin 750 mg BID and demonstrated a decrease in sputum volume and purulence with less dyspnea after 3 days of therapy. However, 5 days later, he is feeling palpitations and has become nauseous. What laboratory value should be checked?

This patient has clinical evidence of theophylline toxicity. Both gastrointestinal complaints (e.g., nausea) and CNS symptoms, including sleep difficulty and nervousness, are consistent with theophylline toxicity. Other adverse reactions associated with methylxanthines are cardiac irritability (tachycardia or arrhythmias) and seizures. All these side effects are dose related. Gastrointestinal intolerance, nervousness, and insomnia can occur at any serum concentration, but increase in frequency when serum concentrations are greater than 15 mcg/mL.

In R.L., the addition of the antibiotic ciprofloxacin to his regimen most likely resulted in a drug interaction causing a rise in his theophylline concentration. The potential for an interaction with theophylline varies among the available fluoroquinolone antibiotics. Drug interactions are dependent on several factors, including the dose of each agent and the baseline serum theophylline concentration. Elevations in the theophylline concentration of 25% are typical with ciprofloxacin interactions, although elevations of 50% have been observed. In R.L., a theophylline concentration should be obtained and further doses withheld until results are known.

In general, theophylline metabolism is associated with significant interpatient and intrapatient variability. Patients should be monitored closely for early signs of toxicity, as well as for the initiation of drugs that potentially may interact. Understanding and recognizing the potential for drug interactions can allow safe and effective therapy with theophylline.

CASE 19-3, QUESTION 3: A theophylline serum concentration is measured for R.L. It is reported as 21 mcg/mL. What action should be taken?

The serum concentration is consistent with the interaction between theophylline and ciprofloxacin reported in the literature. His symptoms do not appear life-threatening at this point, so a conservative approach to treatment is appropriate. Theophylline should be withheld for one dose and then restarted at a lower dose (100 mg BID) until the ciprofloxacin therapy is completed. Alternatively, theophylline could be withheld until the antibiotic treatment is finished or discontinued. As mentioned, theophylline has a narrow therapeutic index and has the potential for serious toxicity as is evidenced by the current case. If the patient is unclear how beneficial the theophylline has been, a trial off of the medication is reasonable. After approximately 2 to 4 weeks, R.L. should be reassessed. If he feels that his chronic symptoms are no different without the drug, it should be discontinued. On the other hand, his symptoms may become more pronounced without the theophylline, and it could then be restarted. Alternatively, it would be reasonable to replace theophylline with an additional long-acting bronchodilator from a different class, in this case a long-acting β agonist. Evidence suggests that the combination of a long-acting anticholinergic and a long-acting β_2-agonist can increase lung function and reduce hyperinflation compared with either agent used alone.[127,128] Salmeterol and formoterol have a similar side effect profile and have similar effectiveness, the only significant difference being that formoterol has a more rapid onset of action. Either salmeterol, one inhalation (50 mcg) every 12 hours, or formoterol, one inhalation (12 mcg) twice daily, would be reasonable options for RL.

COPD has a progressive course, highlighted by a worsening of symptoms with time. Because stepwise therapy is recommended, it is not uncommon to find patients on multiple medications added on in an attempt to alleviate symptoms. Nevertheless, it is important periodically to assess the patient to determine whether all the medications are continuing to provide symptomatic benefit and are still needed. This may result in a step-down approach.

Oxygen Therapy

CASE 19-4

QUESTION 1: P.J., a 62-year-old man with long-standing COPD, presents with worsening dyspnea on exertion. He is currently prescribed combination fluticasone–salmeterol (Advair 250/50 one puff BID), tiotropium (Spiriva 18 mcg one puff every day), and as-needed albuterol (two to four puffs every 4 to 6 hours as needed). P.J. reports excellent adherence with his medications and an evaluation of his inhaler technique reveals he is able to use all three devices correctly. He has undergone pulmonary rehabilitation in the past with some benefit. He is no longer exercising, however. He has smoked 1.5 packs of cigarettes a day for 40 years (60 pack-years), but quit 1 year previously. His most recent FEV_1/FVC ratio is 0.41, and his FEV_1 is 1.25 L, or 38% of predicted. His room air oxygen saturation at rest is 85%. On examination, reduced breath sounds are noted in his chest and he has lower extremity edema. His physician recommended supplemental oxygen; however, he is resistant and wonders what kind of benefit he might receive.

The Nocturnal Oxygen Treatment Trial (NOTT), a randomized controlled study, studied patients with COPD and severe hypoxemia ($Pao_2 \leq 55$ mm Hg, or $Pao_2 \leq 59$ mm Hg associated with polycythemia or peripheral edema).[45] Patients were randomly assigned to receive continuous oxygen or nocturnal oxygen. The primary outcome variable was mortality. Subjects using continuous oxygen had a significantly greater survival and improved end-organ function, including improved cognitive function. The Medical Research Council Study published in 1981, using similar entry criteria, demonstrated a significant survival benefit with continuous supplemental oxygen compared with no oxygen.[46]

On the basis of these studies, supplemental oxygen is currently recommended for severe hypoxemia currently defined as an oxygen saturation less than 88% or Pao_2 equal to or less than 55 mm Hg (oxygen saturation < 90% or $Pao_2 \leq 59$ mm Hg in the presence of polycythemia or clinical evidence of pulmonary hypertension; e.g., peripheral edema). These guidelines (Table 19-8) are used by Medicare and most insurance companies as criteria to determine coverage for supplemental oxygen. This patient should be encouraged to use supplemental oxygen because it is one of the few available interventions that has been associated with improved survival in COPD.

In addition to supplemental oxygen, the patient should be re-enrolled in pulmonary rehabilitation. As mentioned, existing data suggest that this intervention can improve quality of life and exercise tolerance and decrease health care utilization.

Table 19-8

Guidelines for Insurance Reimbursement of Oxygen Therapy in Chronic Obstructive Pulmonary Disease (COPD)

1. Severe hypoxemia at rest[a]:
   $Pao_2 \leq 55$ mm Hg
   Or
   $Pao_2 \leq 59$ mm Hg, with polycythemia or evidence of cor pulmonale
   Or
   Oxygen saturation ≤ 88%
2. Oxygen desaturation ≤ 88% with activity or during sleep[b]

[a] Proven to improve survival.

[b] Efficacy not proven.

Surgical Treatments for COPD

CASE 19-4, QUESTION 2: P.J. is prescribed supplemental oxygen and enrolls in a pulmonary rehabilitation program. These interventions are successful in improving exercise tolerance; however, he presents 12 months later complaining of worsening dyspnea. In addition, although he is compliant with the oxygen, he is wondering whether any other interventions available might improve his lung function and allow him to "get off" of oxygen.

He is reevaluated with pulmonary function studies, which demonstrate a reduced FEV_1/FVC ratio of 0.38 and an absolute FEV_1 of 29% of predicted. In addition, lung volume determinations show severe hyperinflation (TLC = 135% of predicted and air-trapping RV = 292% of predicted). His CXR shows a marked decrease in lung markings in the upper lung zones with vascular crowding in the lower lung fields. What therapeutic options are available for P.J.?

Lung volume reduction surgery, which involves the surgical removal of approximately 30% of the volume of each lung, can significantly improve quality of life, exercise tolerance, and mortality in selected patients with COPD. The National Emphysema Treatment Trial (NETT) demonstrated that patients with severe, upper lobe predominant emphysema who have lung volume reduction surgery have significant benefits in health-related quality of life as well as exercise tolerance.[11] Subjects who also had persistently poor exercise tolerance before surgery appeared to have the most benefit compared with control subjects with similar impairment. These patients also had a mortality benefit.[11] The rationale for the surgery is that removing the areas of the lung most involved with emphysema can improve the physiology of the remaining lung. This includes improvement in expiratory airflow and improved lung elastic recoil as well as improved ventilation–perfusion matching. The major patient selection criteria for lung volume reduction surgery are depicted in Table 19-9. After a successful surgery, patients can have improved gas exchange and may no longer require supplemental oxygen.

The CXR for this patient suggests upper lobe predominant emphysema. This would need to be confirmed with a high-resolution computed tomography scan of the chest. Furthermore, the patient would need to complete a comprehensive pulmonary rehabilitation program before surgery. Only a few centers within the United States are certified by Medicare to perform lung volume reduction surgery, and this could be an important issue for P.J., depending on where he lives. It should be stressed that lung volume reduction surgery is only appropriate for a select group of patients with advanced emphysema.

In patients with severe emphysema, another option is lung transplantation. This intervention has not been shown to decrease mortality, but can improve quality of life and exercise tolerance in carefully selected candidates.[129] Patients considered are those with severe disease, whose life expectancy is less than 5 years, and individuals with an FEV_1 less than 25% of predicted.

Table 19-9

Major Selection Criteria for Lung Volume Reduction Surgery

Moderate to severe airflow obstruction
Hyperinflation
Upper lobe predominant emphysema
Nonsmoker
Rehabilitation potential

Acute and Chronic Rhinitis

Suzanne G. Bollmeier and Dennis M. Williams

	CORE PRINCIPLES	CHAPTER CASES
1	Rhinitis is a common disorder and refers generally to inflammation in the nasal cavity. Common manifestations can include nasal discharge, itching, sneezing, congestion, and postnasal drip. Rhinitis can be caused by allergic, nonallergic, or mixed allergic and nonallergic triggers. Distinguishing the subtype can be helpful in targeting symptomatic treatment and prevention.	**Cases 20-1 (Question 1)** **Cases 20-8 (Question 2)** **Cases 20-9 (Question 1)**
2	Oral antihistamines are the most common therapies used for treating allergic rhinitis. They are convenient and effective for most rhinitis symptoms, including rhinorrhea, sneezing, and itching.	**Cases 20-1 (Question 4)**
3	Second-generation antihistamines are preferred over first-generation agents based on a superior side-effect profile and convenience of dosing.	**Case 20-1 (Question 4)**
4	Intranasal antihistamines offer an alternative to oral agents, with the advantage of efficacy for congestion and for symptoms from some nonallergic causes. Side effects can challenge patient acceptance, however.	**Case 20-1 (Question 5)**
5	Intranasal corticosteroids are the most effective therapies available for treating a variety of rhinitis disorders. They are safe, well tolerated, and are highly effective in reducing itching, sneezing, rhinorrhea, and congestion.	**Cases 20-3 (Question 3)**
6	Proper administration technique is important for intranasal therapies in order to maximize effectiveness and minimize the risk of side effects and toxicities.	**Cases 20-1 (Question 5)** **Cases 20-2 (Question 3)** **Cases 20-3 (Question 7)**
7	Leukotriene modifiers have similar efficacy to oral antihistamines for seasonal allergic rhinitis and may be beneficial for selected patient populations (e.g., those with concomitant asthma or aspirin sensitivity).	**Cases 20-4 (Question 2)**
8	The duration of use of topical decongestants should be limited to 3 to 5 days.	**Case 20-7 (Question 1)**
9	Ophthalmic therapies may be indicated if ocular itching, tearing, and redness are the primary complaint or continue to be bothersome despite	**Case 20-1 (Question 5)**

	appropriate therapy for nasal symptoms associated with rhinitis.	
⑩	Many patients seek complementary and alternative therapies to treat rhinitis conditions, despite limited evidence regarding their effectiveness.	**Cases 20-5 (Question 1)**

DEFINITION

Rhinitis is defined as an inflammatory condition affecting the mucous membranes of the nose and upper respiratory system. In clinical practice, however, the term is used broadly to encompass a heterogeneous group of nasal disorders characterized by periods of rhinorrhea (nasal discharge), pruritus (itching), sneezing, congestion, and postnasal drainage (postnasal drip). These nasal symptoms can be accompanied by ocular symptoms such as redness, itching, and discharge and can be exacerbated by the development or presence of sinusitis. The most common form of rhinitis occurs in response to an allergen, although a variety of other subtypes have been demonstrated.[1–3]

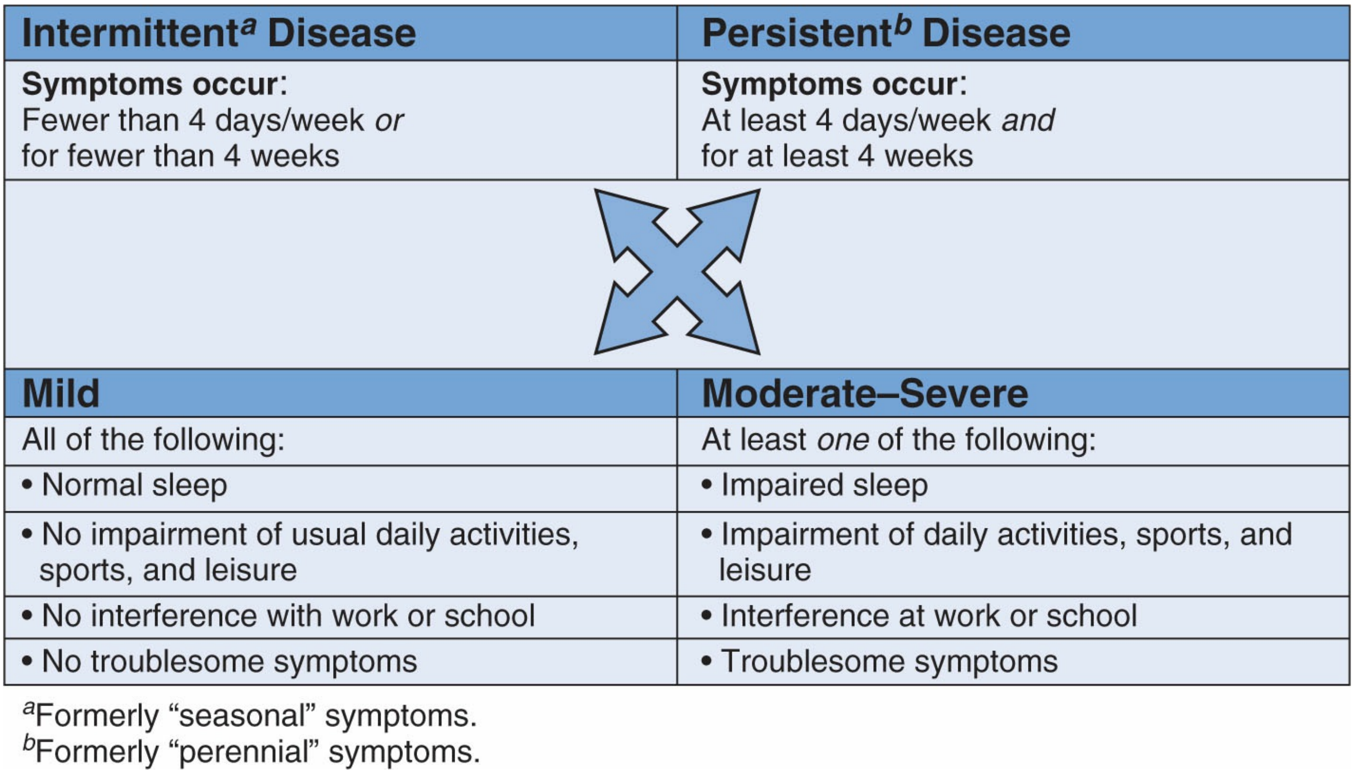
CAUSES AND CLASSIFICATIONS

Rhinitis is not a single disease but rather has multiple causes and underlying pathophysiologic mechanisms.[2,4] Figure 20-1 depicts common causes of acute and chronic rhinitis symptoms, including some conditions that mimic rhinitis (e.g., nasal polyps). The most common cause of acute rhinitis is a viral upper respiratory infection, that is, the common cold.

In most patients, these viral infections are self-limited and require only symptomatic treatment.[2] Nasal foreign bodies are another frequent cause and should be suspected when a pediatric patient presents with acute, unilateral symptoms.[1,3] Hormonal, food, and medication-related rhinitis are also common acute syndromes.[3,5]

Chronic rhinitis can be classified as allergic, nonallergic, or mixed allergic and nonallergic.[2] Allergic rhinitis, the most common subtype, is typically associated with atopy, an inherited tendency to develop a clinical hypersensitivity condition, and its symptoms are a result of immunoglobulin E (IgE)–dependent events.[5] There is not a single, uniform standard for classifying allergic rhinitis. Traditionally, patients have been classified as having seasonal or perennial disease, based on frequency of symptoms and potential offending allergens.[1] An alternative classification system categorizes allergic rhinitis based on severity (e.g., mild, moderate, and severe) and frequency (e.g., intermittent or persistent) of symptoms.[1] This classification system is summarized in Figure 20-2. Clinicians are likely to encounter a combination of these classifications when evaluating the clinical literature and participating in patient care activities.

Several categories exist for nonallergic causes of rhinitis, including nonallergic rhinopathy (previously known as idiopathic rhinitis or vasomotor rhinitis), nonallergic rhinitis with eosinophilia syndrome (NARES), and anatomic abnormalities.[6] Nonallergic rhinopathy refers to symptoms associated with environmental stimuli, including temperature or barometric pressure changes, strong odors, tobacco smoke,[6] stress, or emotional factors.[7] NARES occurs frequently in middle-aged patients, who have no evidence of allergic disease excepting the presence of eosinophils in the nasal smear.[7] Mixed rhinitis is a subset of allergic rhinitis in which features of both allergic and nonallergic diseases are present, and triggers include allergens as well as other irritants.[8] Patients with mixed rhinitis are difficult to differentiate but will typically have more nasal symptoms from nonallergic triggers.[8] The presence of mixed disease should not be overlooked when evaluating the presentation of a patient or assessing the response to therapy.



Intermittent[a] Disease	Persistent[b] Disease
Symptoms occur: Fewer than 4 days/week *or* for fewer than 4 weeks	**Symptoms occur:** At least 4 days/week *and* for at least 4 weeks
Mild	**Moderate–Severe**
All of the following:	At least *one* of the following:
• Normal sleep	• Impaired sleep
• No impairment of usual daily activities, sports, and leisure	• Impairment of daily activities, sports, and leisure
• No interference with work or school	• Interference at work or school
• No troublesome symptoms	• Troublesome symptoms

[a] Formerly “seasonal” symptoms.
[b] Formerly “perennial” symptoms.

Figure 20-2 ARIA classification of allergic rhinitis. ARIA, Allergic Rhinitis and its Impact on Asthma. (Source: Bousquet J et al. Allergic rhinitis and its impact on asthma [ARIA] 2008 update [in collaboration with the World Health Organization, GA(2)LEN and AllerGen]. Allergy. 2008;63[Suppl 86]:8.)

EPIDEMIOLOGY AND IMPACT

Prevalence rates for rhinitis are difficult to quantify because the condition is often undiagnosed, different definitions are used, and data collection methods vary.[9] A conservative estimate suggests that the prevalence of allergic rhinitis is approximately 15% (via physician diagnosis), but it may be as high as up to 30% in adults (and even more children), based on self-reported nasal symptoms[2] making it the fifth most common chronic illness in the United States.[1] According to recent survey data, the number of children with respiratory allergies in the past 12 months was nearly 8 million, and adults reporting a diagnosis of hay fever in the past 12 months was 17.8 million.[10]

In recent decades, prevalence in Western societies has increased, and studies from around the world are reporting similar trends.[5,11] Although studies have traditionally reported a 3:1 ratio of allergic to nonallergic rhinitis, recent data suggest that up to 87% of patients may experience symptoms from mixed causes.[7]

Rhinitis can lead to poor sleep,[12] decreased work productivity,[13] headache or fatigue,[14] irritability, and rhinitis patients are typically less attentive in school because of decreased concentration, and difficulty learning.[14] Although many patients will self-treat their rhinitis symptoms, visits to provider offices are common.[15] A patient with allergic rhinitis will visit the provider approximately three more times per year and fill nine more prescriptions yearly compared to a patient without rhinitis.[16]

Although rhinitis does not lead to the mortality associated with some illnesses, its prevalence and negative health impact make it an important health problem in the United States. Allergic diseases are a frequent contributor to health-related absenteeism.[17] It is estimated that 10.7 million workdays are missed because of allergic rhinitis in the United States per year.[17]

ANATOMY AND PHYSIOLOGY

The external nose is pyramidal and consists of paired nasal bones and associated cartilage. Its base has two elliptical-shaped openings called nares, or nostrils. Internally, a septum separates the nasal cavity into two halves and consists of bone and cartilage covered by a mucosal membrane.[18]

The membranes of the nasal cavity consist primarily of pseudostratified ciliated columnar epithelial cells with mucus-producing goblet cells interspersed among them.[18] The mucus lining serves as a protective shield against bacterial and viral infections.[18] The tiny cilia beat rhythmically to transport mucus across the upper airway membrane to the nasopharynx. In addition, respiratory secretions residing on these mucous membranes contain immunoglobulin A (IgA), which serves as an immunologic defense.[18]

The autonomic nervous system controls the vascular supply and the secretion of mucus to the nasal membrane. Sympathetic activation results in vasoconstriction, which decreases nasal airway resistance.[18] Parasympathetic stimulation results in glandular secretion and nasal congestion.[18] The mucosa is also innervated by the nonadrenergic–noncholinergic system. Neuropeptides from these nerves (e.g., substance P and neurokinins) play a role in vasodilation, mucus production, and inflammation,[18] although their significance is unclear. The trigeminal nerve also provides sensory innervation.[18] The primary functions of the nose and upper airway are smell, speech, and the exchange of air between the internal and external environments.[18] These processes are disrupted in the presence of inflammation, increased mucus, and congestion.

ETIOLOGY OF ALLERGIC RHINITIS

Genetic, environmental, and lifestyle influences are associated with the development of allergic rhinitis.[19] Candidate genes have not been identified;[19] however, atopy is a significant inheritable factor, and the risk of a child experiencing allergic symptoms is approximately 44% to 50% with one atopic parent[2,5] and is even more likely with two atopic parents.[5] Environmental exposures, particularly early in life, are also important in the development of symptoms.[20] In addition, lower socioeconomic status may be a risk factor for development of allergic rhinitis.[20]

One etiologic theory, referred to as the hygiene hypothesis, suggests that the initial differentiation of lymphocytes early in life has either positive or negative influences on the development of subsequent allergies. In the normal development of the immune system, the lymphocytes differentiate into helper T (either T_H1 or T_H2) cells based on environmental stimuli. Factors associated with a T_H1 (allergy protective) response include exposures to various bacteria and viruses, the presence of older siblings, and early attendance in day care. Factors associated with a T_H2 (predisposition to allergies) response include environmental exposures to house dust mites, cockroaches, or early, frequent antimicrobial use.[4,5]

In patients with seasonal or intermittent allergic rhinitis, grass and tree pollens and airborne mold spores are the most common allergens.[21] Although the pollen season varies with geographic location, types of grasses, trees, and weeds, it can be problematic for many people during active pollination. In the United States, ragweed is a primary cause of intermittent symptoms.[21]

In patients with persistent allergic rhinitis, the major allergens are house dust mites, indoor molds, animal dander, and cockroach antigen. Another common cause is occupational exposure, in which symptoms can be precipitated by agents such as flour, wood, paint, grain, latex, and detergents.[5]

PATHOPHYSIOLOGY

The pathogenesis of allergic rhinitis and asthma includes numerous areas of commonality. Inflammation is a central mechanism, and the role of cytokines is similar. This has led many scientists and clinicians to adopt the concept of “one airway, one disease.”[4] Further evidence for this association includes the fact that rhinitis is a known risk factor for asthma,[5] some patients with rhinitis exhibit bronchial hyperresponsiveness,[4] and treating allergic rhinitis can improve asthma.[2,4] Consequently, some treatment strategies, including pharmacotherapy, have a role in both rhinitis and asthma.

Allergic rhinitis is characterized by an IgE-mediated response that involves three primary steps: sensitization, early-phase events, and late-phase events.[4] This process is depicted in Figure 20-3. The nonallergic pathogenic course is less well understood. It is not IgE-mediated, although in some subtypes inflammatory cells and mediators can cause similar effects to those seen in the allergic form.[6]

Sensitization

In atopic patients, sensitization to an allergen occurs after initial exposure causing production of IgE antibodies. These antibodies bind to receptors on mast cells. Upon subsequent exposure, activation of an inflammatory response is initiated because of the cross-linking of the allergen, IgE antibody, and the mast cell.[5]

Early Response

After initial exposure, antigen-presenting cells of the immune system react to allergens deposited on the nasal mucosa.[5] Mast cells and other cells, such as basophils,[14] then release both new and preformed chemotactic[14] inflammatory mediators, such as histamine, which can cause localized inflammation.[4] Symptoms associated with this early response can occur within minutes, including sneezing, rhinorrhea, and nasal itching.[5] Histamine receptors (H_1) are present throughout the nasal mucosa and airway. Their activation results in vascular engorgement, leading to nasal congestion and rhinorrhea.[14] In addition, histamine stimulates sensory nerves of the parasympathetic nervous system in the upper airway causing other inflammatory mediators such as basophils,[5] eosinophils, lymphocytes, macrophages, and dendritic cells to migrate to the upper airway, contributing to a late-phase response.[14]

Late Response

Up to one-third of patients with allergic rhinitis also experience a late response that develops approximately 4 hours after initial exposure and may persist for up to 8 hours.[22] In this phase, the nature of inflammation is even more complex, and nasal congestion is a prominent feature.[4] Numerous cells and mediators, including T_H2 lymphocytes, cytokines, basophils, eosinophils, neutrophils, macrophages, and leukotrienes, play important roles.[4] These additional mediators, attracted to the area through chemotaxis, sustain the inflammatory response.[4] Also, some chemotactic proteins can cause damage to the airway epithelium and expose local nerve fibers.[4] Continued exposure to the offending allergen can also prolong the late-phase reaction.

CLINICAL PRESENTATION AND ASSESSMENT OF RHINITIS

The diagnosis of rhinitis is not defined by one specific laboratory test; rather, it is related to the coordinated results of a thorough patient interview, including medication history, pertinent physical examination, and a limited number of relevant laboratory assessments.

Risk Factors

Several elements increase the risk of developing allergic rhinitis. Parental history,[2] introduction of formula in infancy, exposure to maternal smoking at less than 1 year of age, serum IgE levels >100 IU/mL before 6 years of age, food allergies,[14] ethnic origin other than white European, environmental pollution, birth during pollen season, no older siblings, late entry into nursery or preschool, and exposure to indoor allergens such as animal dander and dust mites are risk factors.[5]

History, Signs, and Symptoms

A history should be obtained from the patient that includes details of the onset, character, frequency, duration, and severity of the patient’s symptoms and any identifiable factors that provoke or relieve these symptoms.[5] Past medical history (including age of onset of symptoms) and family history (e.g., atopy) are also helpful.[5]

Both allergic and nonallergic forms of rhinitis are common and can potentially coexist.[2] Diagnostic criteria suggestive of allergic rhinitis include nasal itching, sneezing, nasal congestion, clear rhinorrhea, and occasionally a decreased sense of smell.[5] Symptoms of allergic conjunctivitis include itchy, watery eyes,[5] which occur in approximately 50% to 70% of allergic rhinitis patients. Their presence can be used to differentiate allergic rhinitis from other forms.[5] Persistent congestion and/or rhinorrhea[7] in response to nonallergic triggers like weather changes, perfumes/odors, and smoke/fumes[6] are consistent with nonallergic rhinitis. The negative impact of rhinitis on a patient’s quality of life can be substantial, and it is important to assess this during the patient interview. Symptoms and symptom-induced interference with necessary (i.e., work, school) and enjoyable (e.g., hobbies, family events) activities can lead to patient anger, sadness, irritation, and withdrawal.[5] The questions listed in Figure 20-4 provide a guide to collecting the information needed to initiate and modify therapy based on the underlying causes of the rhinitis symptoms.

Diagnosis

PHYSICAL EXAMINATION

During a physical examination for rhinitis, the patient’s nose should be inspected for position of the septum, appearance of the nasal mucosa, secretions, and any growths.[3] Common physical characteristics of patients with allergic rhinitis are clear nasal discharge and swollen nasal membranes.[4]

The patient’s eyes, ears, throat, and chest should also be examined. Chronic mouth breathing because of nasal obstruction can cause recognizable facial characteristics (e.g., adenoid face, allergic shiners, and nasal crease) and dental abnormalities.[1,14]

1. Which of the common symptoms of rhinitis is the patient experiencing?
    - Sneezing, nasal itching, runny nose, nasal congestion, postnasal drip, altered sense of smell, watery eyes, itching eyes, ear “popping”
2. What color are the nasal secretions?
    - Clear, white, yellow, green, blood-streaked, rusty brown
3. When did the symptoms first appear?
    - Infancy, childhood, adulthood
4. Were the symptoms associated with a change in state/environment?
    - After a viral upper respiratory infection, after a traumatic blow to the head or face, upon moving into/visiting a new dwelling, after obtaining a new pet
5. How often do the symptoms occur?
    - Daily, episodically, seasonally, constantly
6. For how long has this symptom pattern persisted?
    - Days, weeks, months, years
7. Which factors or conditions precipitate symptoms?
    - Specific allergens, inhaled irritants, climatic conditions, food, drinks
8. Which specific activities precipitate symptoms?
    - Dusting, vacuuming, mowing grass, raking leaves
9. Are other members of the family experiencing similar symptoms?
10. Which of the following are prevalent in the household?
    - Carpeting, heavy drapes, foam or feather pillows, stuffed toys, areas of high moisture (basements, bathrooms), tobacco use (by patient or others), pets
11. Does the patient have other medical conditions that can cause similar symptoms?
12. Is the patient taking any medications that might cause or aggravate these symptoms?
13. What prescription and nonprescription medications have been used for these symptoms in the past? Were they effective? Did they cause any unwanted effects?
14. What is the patient's occupation?
15. What are the patient's typical leisure activities?
16. To what extent have the symptoms interfered with the patient's lifestyle (i.e., are they disabling or merely annoying)?
    - Greatly, somewhat, not much

Figure 20-4 Patient history interview.

Laboratory Tests

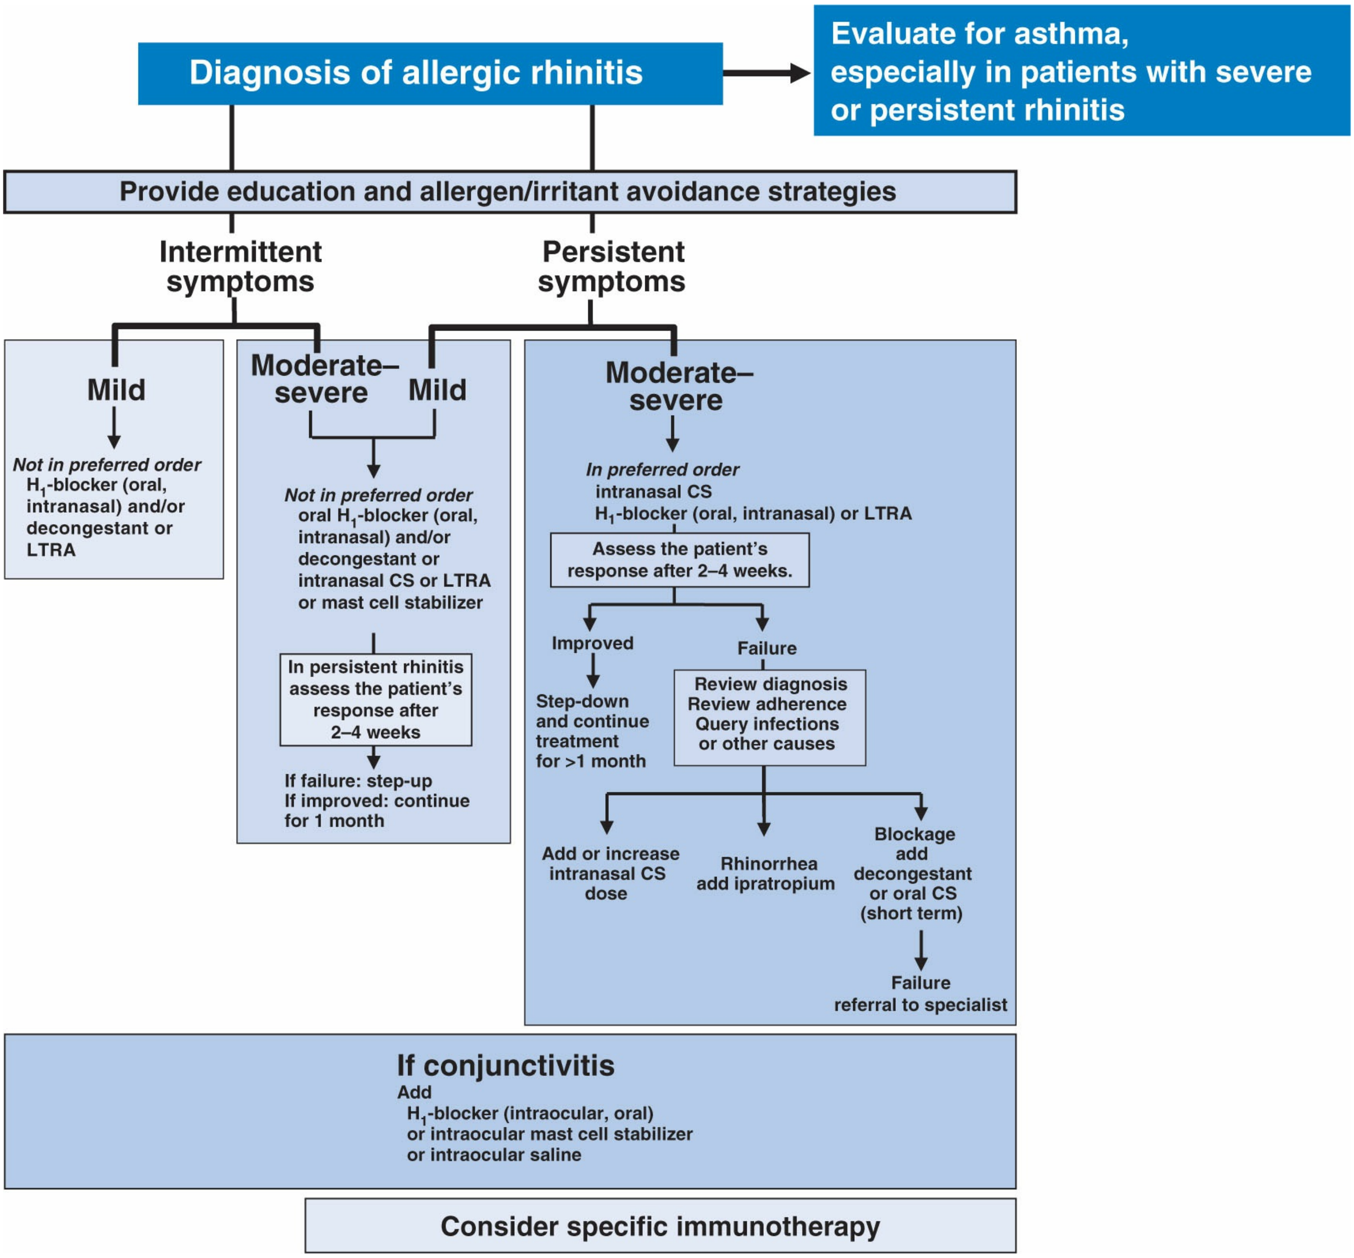
Several diagnostic tests are available for confirming a diagnosis of allergic rhinitis in patients who present with a suggestive history and symptoms. Microscopic examination of nasal secretions can be performed, but consensus on their usefulness is lacking.[1] In allergic conditions, the clinician would expect numerous eosinophils to be present in the sample; however, this could also be true of NARES or nasal polyps.[23]

Immediate hypersensitivity skin tests are used to demonstrate an IgE-mediated response of the skin to an allergen.[1] A variety of skin test methods are available; however, the skin-prick/puncture technique (in which the wheal-and-flare reaction is evaluated 15 to 20 minutes after allergen administration) is preferred.[1] A primary point of differentiation between pure allergic versus nonallergic disease is the presence of a serum IgE level greater than 100 international units/mL (especially before age 6), which is consistent with atopy.[5] However, a clinical diagnosis of either allergic or nonallergic disease is often made in the absence of a serum IgE and is based on the nature of symptoms and triggers.

OVERVIEW OF TREATMENT

There are two primary guideline resources available that summarize evidence and expert opinion regarding the diagnosis and management of allergic rhinitis. The first, from the America Academy of Otolaryngology, Head and Neck Surgery Foundation, was published in early 2015 by a panel consisting of 20 members representing experts in the field of allergy and immunology.[1] In addition, evidence linking asthma and allergic rhinitis epidemiologically, pathologically, and physiologically has been published, suggesting that upper respiratory allergic disorders and asthma represent components of a single inflammatory airway syndrome.[4] This prompted the development and subsequent update of the Allergic Rhinitis and Its Impact on Asthma (ARIA) guidelines in 2010, which provide direction for clinicians caring for patients with both conditions.[24] This document includes information about the use of complementary and alternative therapies, rhinitis in athletes, and grading the evidence used to establish the guidelines.[24]

The treatment goals for rhinitis are to prevent or relieve symptoms, and improve quality of life without adverse drug effects or excessive cost. These goals should be achievable through the establishment of a therapeutic partnership with a competent and caring clinician. With appropriate treatment, the patient should be able to maintain a normal lifestyle and perform desired activities. Common management strategies include patient education, allergen and irritant avoidance, and pharmacotherapy.[1,3,4,14] Figure 20-5 depicts an algorithm for the general management of allergic rhinitis.



Diagnosis of allergic rhinitis
Evaluate for asthma, especially in patients with severe or persistent rhinitis
Provide education and allergen/irritant avoidance strategies
Intermittent symptoms
Persistent symptoms
Mild
Not in preferred order
H1-blocker (oral, intranasal) and/or decongestant or LTRA
Moderate–severe
Mild
Not in preferred order
oral H1-blocker (oral, intranasal) and/or decongestant or intranasal CS or LTRA or mast cell stabilizer
In persistent rhinitis assess the patient's response after 2–4 weeks
If failure: step-up
If improved: continue for 1 month
Moderate–severe
In preferred order
intranasal CS
H1-blocker (oral, intranasal) or LTRA
Assess the patient's response after 2–4 weeks.
Improved
Failure
Step-down and continue treatment for >1 month
Review diagnosis
Review adherence
Query infections or other causes
Add or increase intranasal CS dose
Rhinorrhea add ipratropium
Blockage add decongestant or oral CS (short term)
Failure referral to specialist
If conjunctivitis
Add
H1-blocker (intraocular, oral)
or intraocular mast cell stabilizer
or intraocular saline
Consider specific immunotherapy

Figure 20-5 Treatment algorithm for allergic rhinitis. Treatment should be directed at predominant symptoms (i.e., for eye symptoms in the absence of other symptoms use ophthalmic preparation). Prevention strategies are more effective than treatment strategies. For intermittent symptoms, begin treatment several weeks before antigen exposure and discontinue when no longer needed. CS, corticosteroid; LTRA, leukotriene receptor antagonist (leukotriene modifier). (Source: Bousquet J et al. Allergic rhinitis and its impact on asthma [ARIA] 2008 update [in collaboration with the World Health Organization, GA(2)LEN and AllerGen]. Allergy. 2008;63[Suppl 86]:8.)

Patient Education

Patients should be educated about their rhinitis. Considerations for patient education include instruction about the disease and specific triggers, the range of symptoms, the role of various treatments, and suitable technique for nasal drug delivery.[5] A discussion of allergen and trigger avoidance is also important.

Allergen and Irritant Avoidance

Although the benefit of allergen avoidance has proved difficult to document, this strategy is considered central in a comprehensive management plan for allergic rhinitis.[1,5,6,14] Various strategies for minimizing exposure to known allergens (e.g., pollens, house dust mites, molds, animal dander, and cockroaches) are commonly used for prevention. Because little evidence supports a single physical or chemical intervention to reduce allergen exposure, a multifaceted approach should be used.[1] Efforts to reduce exposure to irritants (e.g., tobacco smoke, indoor, or outdoor pollutants) should also be recommended, because it is anticipated that this would have similar benefits as allergen avoidance.[3]

Pharmacotherapy

Several classes of medications are used in the management of rhinitis disorders. Choices should be based on goals of treatment, safety, efficacy, cost-effectiveness, adherence, severity, comorbidity, and patient preferences. Common therapies are administered either orally or topically and used on a regular schedule or on an as-needed basis.[1] Few cost-effectiveness data exist comparing the classes of therapy, except the second-generation antihistamines (SGAs),[25] nasal corticosteroids,[26] and subcutaneous immunotherapy,[27] which have been shown to be cost-effective. Table 20-1 summarizes the effectiveness of agents for specific symptoms used in the treatment of allergic rhinitis.

ANTIHISTAMINES

Antihistamines are the most common treatment for allergic rhinitis and are effective for relieving sneezing, itching, and rhinorrhea. They also diminish eye symptoms but, when taken orally, have minimal effects on nasal congestion.[2] Although first-generation antihistamines (FGAs) are efficacious, their use is limited by anticholinergic, sedative, and performance-impairing effects, which challenge their cost-effectiveness.[6] As a result, SGAs are preferred over FGAs in most cases where an antihistamine is desired.[1] Antihistamines are available in oral, ophthalmic, and intranasal formulations and can also be found in combinations with oral decongestants. They are most effective when administered before allergen exposure.

Although oral antihistamines (Table 20-2) represent the most commonly used therapy for allergic rhinitis, there is evidence that intranasal antihistamines are equal or superior in efficacy to oral agents. Further, they appear to relieve symptoms of mild congestion, which is not a feature of oral antihistamines.[1] Intranasal antihistamines work quickly; within 15 to 30 minutes but may be complicated by a bitter taste.[1] The improved efficacy of intranasal antihistamines over oral agents in certain rhinitis conditions may be because of direct administration to the affected site. Olopatadine 0.6%, Azelastine 0.1%, and 0.15% are Food and Drug Administration (FDA) approved for treatment of both seasonal and perennial allergic rhinitis in patients >6 years old.[1]

Table 20-1

Effectiveness of Agents[a] Used in the Management of Allergic Rhinitis

	Rhinorrhea	Nasal Pruritus	Sneezing	Nasal Congestion	Eye Symptoms	Onset
Antihistamines						
Nasal	Moderate	High	High	Moderate	0	Rapid
Ophthalmic	0	0	0	0	Moderate	Rapid
Oral	Moderate	High	High	0/Low	Low	Rapid
Decongestants

		the evening			
Desloratadine[d] (Clarinex)	5 mg once daily	Children 6–11 years: 2.5 mg once daily Children 1–5 years: 1.25 mg once daily Children 6–11 months: 1 mg once daily	±	0	±

[a] Many oral antihistamines are sold as combination products with the oral decongestants pseudoephedrine and phenylephrine. The addition of the decongestant may alter the dosing scheme for the product. As of 2005, pseudoephedrine products have been placed behind the pharmacy counter in the United States. Federal law limits the quantity available for purchase and requires a signature and photo identification. Individual states may have additional restrictions regarding the sale of pseudoephedrine. Consult local boards of pharmacy for details.

[b] Some oral antihistamines are available in both short-acting and extended- or sustained-release formulations. Refer to package insert for specific dosing instructions for long-acting products.

[c] In 2008, the FDA issued an advisory alert recommending that OTC cough and cold agents (e.g., products containing antitussives, expectorants, decongestants, and antihistamines) not be used in infants and children younger than 2 years of age because of the potential for serious and possibly life-threatening adverse events (http://www.fda.gov/ForConsumers/ConsumerUpdates/ucm048682.htm). More recently, in October 2008, leading pharmaceutical manufacturers voluntarily modified product labels on OTC cough and cold preparations to state "do not use" in children younger than 4 years of age (http://www.fda.gov/drugs/guidancecomplianceregulatoryinformation/enforcementactivitiesbyfda/selecte Furthermore, in 2011, the FDA removed unapproved prescription allergy products from the market because they had not been proven to meet standards for safety, effectiveness, and quality (http://www.fda.gov/drugs/guidancecomplianceregulatoryinformation/enforcementactivitiesbyfda/selecte

INTRANASAL CORTICOSTEROID AGENTS

Intranasal corticosteroids are the most effective medication class for the treatment of allergic rhinitis, and are particularly useful for more severe or persistent symptoms.[1,6] Although achieving optimal outcomes depends on the patient's ability to use the device correctly, if administered as intended, these agents are appropriate for all symptoms, are generally well tolerated, and have few adverse effects.[24] They are most beneficial when dosed on a regular schedule; some evidence indicates, however, that they are effective when used on an as-needed basis.[1,6] Intranasal corticosteroids are also useful for treating nonallergic rhinitis[6] and some are available over-the-counter (OTC).

LEUKOTRIENE MODIFIERS

Leukotriene modifiers are effective in relieving many of the nasal symptoms of allergic rhinitis such as day-time congestion, rhinorrhea, pruritis, sneezing, and improves sleep as well as congestion on awakening.[4] Current guidelines recommend against utilizing this class of drugs as first-line.[1] They may have a role as an alternative option for preschool-aged children and adults with seasonal allergic rhinitis, but are not recommended for adult patients with perennial allergic rhinitis.[24] In addition, selected patients might benefit from the combination of an antihistamine and a leukotriene modifier,[14] such as those with concomitant asthma and allergic rhinitis.[1,28] There is no evidence that these agents are helpful for symptoms from nonallergic causes.

CROMOLYN

Intranasal cromolyn, a nonsteroidal agent, acts as a mast-cell stabilizer and, although safe, it is generally less efficacious than other therapies and only useful for symptoms related to allergic causes. It should be administered multiple times daily and requires several weeks to be effective.[5] It is best reserved for prophylaxis before exposure to a known allergen[14,28] and because of its excellent safety profile[28] for use by children or in pregnancy.[29]

DECONGESTANTS

Oral and nasal decongestants (Table 20-3) can effectively reduce nasal congestion by working on α-adrenergic receptors.[28] Oral agents are often combined with antihistamines and are generally well tolerated, but their use can lead to insomnia, nervousness, urinary retention, hypertension, and even palpitations which may be problematic for some patients.[30] Subsequently, these agents should be used with caution in elderly patients and in those with hyperthyroidism, cardiovascular disease, diabetes, glaucoma, or those who are pregnant.[30] Nasal agents are not typically associated with these effects, but should be limited to short-term use to avoid rebound nasal congestion.[28] Because pseudoephedrine is used in the illegal manufacture of methamphetamine, there are now restrictions on the sale of nonprescription formulations.[30] Also, questions regarding the efficacy of phenylephrine[30] have resulted in challenges to the optimal use of oral decongestants.

ANTICHOLINERGIC AGENTS

Intranasal ipratropium bromide is an anticholinergic agent effective in reducing watery, nasal secretions in allergic rhinitis, nonallergic rhinitis, and viral upper respiratory infections.[28] Anticholinergic agents have no significant effects on other symptoms.

OPHTHALMIC THERAPIES

Ophthalmic products used to treat symptoms of allergic conjunctivitis include antihistamines, decongestants, mast-cell stabilizers, and nonsteroidal anti-inflammatory agents. These agents are effective in reducing ocular symptoms and may be used in combination with oral and intranasal agents.

IMMUNOTHERAPY

Specific allergen immunotherapy (SIT) should be considered for patients with IgE-mediated disease,[3] who have severe symptoms despite optimal pharmacotherapy,[2,5] those who experience side effects from drugs restricting their treatment choices,[5] or those who cannot avoid allergen exposure.[3] The clinical efficacy of immunotherapy by subcutaneous injection (SCIT), sometimes called "allergy shots," is well established[2] and is the only treatment that can offer the potential for disease remission.[1–3] Traditional SCIT presents some disadvantages, however, such as cost, adherence, and rare adverse systemic reactions.[1,31] Because regular injections can be unacceptable to some patients, alternative methods of delivering antigens, such as nasal, oral, bronchial, and sublingual immunotherapy (SLIT) have been investigated.[31] The oral, nasal, and bronchial routes have been abandoned because of lack of clinical efficacy or safety concerns.[31,32] Efficacy of immunotherapy given sublingually (SLIT) has been documented and the tablet form received FDA approval in April, 2014.[1,33] See Table 20-4 for details. There are potential adverse effects including local reactions such as oral itching[1] and swelling of the lips and mouth.[32] Systemic reactions can occur from both SCIT and SLIT and include urticaria, gastrointestinal upset, wheezing, and anaphylaxis.[1] Because of the potential for these reactions, SCIT is to be administered in the providers office; however, after the first dose of SLIT, it may be given at home (on a daily basis).[2] Providers are urged to prescribe and educate patients on how to use injectable epinephrine for emergency use and SLIT should not be given to patients with uncontrolled asthma or those on β-blocking agents.[29]

Table 20-3

Decongestants[a],[b] Commonly Used in Allergic Rhinitis

Generic Name (Example Brand Product)	Adult Dose	Pediatric Dose[c]
Oral[a]		
Pseudoephedrine (Sudafed)	60 mg every 4–6 hours (max 240 mg/day)	Children 6–11 years: 30 mg every 4–6 hours (max 120 mg/day) Children 2–5 years: 15 mg every 4–6 hours (max 60 mg/day)
Phenylephrine (Sudafed PE)	10–20 mg every 4 hours (max 120 mg/day)	Children 6–11 years: 10 mg every 4 hours (max 60 mg/day)
Topical[d]		
Naphazoline (Privine)	0.05% solution: 1–2 drops or	Children <12 years: avoid, unless

	sprays/nostril every 6 hours	under physician direction
Phenylephrine (Neo-Synephrine)	0.25%–1.0% solution: 2–3 sprays or drops/nostril every 3–4 hours	Children 6–11 years: 2–3 sprays or drops (0.25% solution)/nostril every 4 hours Children 2–5 years: 2–3 drops (0.125% solution) into each nostril not more than every 4 hours
Oxymetazoline (Afrin)	0.05% solution: 2–3 sprays/nostril every 10–12 hours	Children 6–12 years: 2–3 sprays/nostril every 12 hours
Xylometazoline	0.1% solution: 2–3 sprays into each nostril every 8–10 hours	Children 2–12 years: 1–2 sprays (0.05% solution) into each nostril every 8–10 hours

[a] Many oral decongestants are sold as combination products with the oral antihistamines. The addition of the antihistamine may alter the dosing scheme for the product. As of 2005, pseudoephedrine products have been placed behind the pharmacy counter in the United States. Federal law limits the quantity available for purchase to 9 g/month, 3.6 g/day with signature and photo identification. Individual states may have additional restrictions regarding the sale of pseudoephedrine. Consult local boards of pharmacy for details.

[b] Some oral decongestants are available in both short-acting and extended- or sustained-release formulations. Refer to package insert for specific dosing instructions for long-acting products. Note that some extended-release formulations are not recommended for children younger than 12 years of age.

[c] In 2008, the FDA issued an advisory alert recommending that OTC cough and cold agents (e.g., products containing antitussives, expectorants, decongestants, and antihistamines) not be used in infants and children younger than 2 years of age because of the potential for serious and possibly life-threatening adverse events(**http://www.fda.gov/ForConsumers/ConsumerUpdates/ucm048682.htm**). More recently, in October 2008, leading pharmaceutical manufacturers voluntarily modified product labels on OTC cough and cold preparations to state “do not use” in children younger than 4 years of age. Furthermore, in 2011, the FDA removed unapproved prescription allergy products from the market because they had not been proven to meet standards for safety, effectiveness, and quality(**http://www.fda.gov/drugs/guidancecomplianceregulatoryinformation/enforcementactivitiesbyfda/se**

[d] Limit duration of treatment to less than 5 days to minimize risk of rebound congestion. Topical decongestants should never be used in preschoolers[24] or infants because of possible toxicity.[14]

Table 20-4

Sublingual Tablet Immunotherapy

Drug Name	Allergen	Ages approved for (in years)	Dosing	Dosing considerations
Ragwitek	Ragweed pollen	18–65	1 tablet SL once daily	Initiate treatment at least 12 weeks before expected onset of each ragweed pollen season and continue throughout pollen

				season.
Oralair	Mixed grasses: Sweet Vernal, Orchard, Perennial Rye, Timothy, and Kentucky Bluegrass	10–65	Adults: 300 IR SL once daily 10 to 17 years of age: 100 IR sublingually on day 1, then 200 IR on day 2, and then 300 IR once daily thereafter Remove sublingual tablet from blister immediately prior to administration	Initiate treatment 4 months before expected onset of each grass pollen season and continue throughout pollen season
Grastek	Timothy grass	5–65	5 and older: 2,800 BAU SL once daily Remove sublingual tablet from blister immediately prior to administration	Initiate treatment at least 12 weeks before expected onset of each grass pollen season and continue throughout pollen season May be taken daily for 3 consecutive years (including intervals between grass pollen seasons) In clinical trials, treatment interruptions of up to 7 days were allowed

Administer first dose in a health care setting because of the potential for allergic reactions; monitor patient for 30 minutes after first dose. If well tolerated, subsequent doses may be taken at home. Auto-injectable epinephrine should be made available to patients.

Place tablet(s) under tongue until completely dissolved (at least 1 minute) and then swallow.

Wash hands after handling tablet. Avoid food or beverage for 5 minutes following dissolution of tablet (to prevent the swallowing of allergen extract).

SL, sublingual; IR, index of reactivity; BAU, bioequivalent allergy unit.

ANTI-IgE THERAPY

Omalizumab is a recombinant humanized monoclonal anti-IgE antibody that complexes free circulating IgE in the body. The complex cannot interact with mast cells and basophils, thus reduces IgE-mediated allergic reactions.[28] When administered as a subcutaneous injection once or twice monthly, omalizumab has been shown to decrease nasal symptoms[4] for both seasonal and perennial allergic rhinitis.[28] Currently, this therapy is approved only for people 12 years of age and older with moderate to severe allergy-related asthma inadequately controlled with inhaled corticosteroids. Omalizumab is also approved for patients with chronic idiopathic urticaria who remain symptomatic despite H_1 antihistamine treatment. This product has a high cost (estimated to be between $6,400 and $32,000 per patient per year).[28] The product has a boxed label warning to alert users that omalizumab can cause potentially life-threatening allergic reactions after any dose, up to 24 hours after the dose is given and even if there was no reaction to the first dose.[34] The FDA has also received reports regarding a slightly higher rate of heart and brain blood vessel problems as well as a potential increased risk of certain cancers, which needs to be monitored.[35]

Special Considerations of Medications in Pregnancy

The majority of data about the risks of various pharmacotherapies are derived from animal studies. There are limited human data; however, cohort and case control studies have been used to support therapeutic decision-making. Antihistamines, intranasal steroids, and cromolyn are considered safe to use during pregnancy.[3] Oral decongestants should generally be avoided,[3] although topical decongestants may be used on a short-term basis.[29] With limited human data available, oral montelukast is categorized as "probably compatible" with pregnancy;[29] however, generally, topical drugs are recommended over systemic therapy. Patients currently using immunotherapy may continue; however, initiation or an increased dose of immunotherapy is contraindicated.[3]

Nondrug Therapies

Supportive care is the foundation of treatment for patients with symptoms of rhinitis.[1] These strategies can be helpful during an acute worsening of symptoms as well as for the patient who suffers chronically. Supportive care can ameliorate discomfort, relieve mild symptoms, and assist with side effects from pharmacotherapies. Examples include the application of compresses to the sinuses or external nasal passages and humidification of mucous membranes with artificial tears or nasal saline solutions. Many patients with chronic symptoms of rhinosinusitis report subjective improvement with nasal saline douching,[3,5] or irrigation.

SPECIFIC THERAPEUTIC OPTIONS

Antihistamine Therapy

DIAGNOSIS OF ALLERGIC RHINITIS

CASE 20-1

QUESTION 1: L.B. is a 57-year-old man with a history of hypertension for 10 years and intermittent allergic rhinitis since childhood (confirmed sensitivity to birch tree pollen via skin testing). L.B. presents with complaints of nasal itching, sneezing, clear rhinorrhea, and stuffiness. He usually experiences similar symptoms, as well as ocular itching every spring, but has noticed that the problem has become persistent since he moved into an older home in the historic district of town. In the past, L.B. has successfully self-medicated his seasonal symptoms with an OTC antihistamine and decongestant (diphenhydramine 50 mg and pseudoephedrine 60 mg twice a day to 4 times a day as needed for symptoms), although "nothing seems to help much with the itchy eyes." L.B.'s hypertension has been well controlled with hydrochlorothiazide 25 mg every morning and amlodipine 10 mg every day. He denies any other medical problems, is afebrile, and his blood pressure is 128/82 mm Hg. He has no history of adverse drug reactions or drug allergies. He does not smoke, but drinks alcohol socially. What elements of L.B.'s presentation indicate a probable diagnosis of allergic rhinitis?

L.B. is exhibiting the classic symptoms of persistent (perennial) allergic rhinitis with intermittent (seasonal) exacerbations: nasal itching, sneezing, watery (often profuse) rhinorrhea, and congestion.[4] His history of positive skin tests and that his symptoms previously responded to antihistamine or decongestant[2] also support the diagnosis. In the past, L.B. has experienced symptoms predictably at the onset of the tree pollination season, with only minimal symptoms during the remainder of the year. Moving into an older home, however, has likely triggered latent sensitivities to dust mite allergens and mold spores. A treatment approach can be developed based on these presumptions. If this strategy is not effective, skin testing or additional laboratory assessments are warranted.

ALLERGEN AVOIDANCE MEASURES

CASE 20-1, QUESTION 2: What allergen avoidance strategies could L.B. use to minimize his exposure to triggers?

Allergen avoidance is important for reducing symptoms in patients with known sensitivities. Avoiding these triggers should lead to an improvement of symptoms; however, little evidence supports the effectiveness of a single physical or chemical method.[24] To achieve effective control, a multifaceted approach to the control of environmental triggers is usually needed.[24] Although total allergen avoidance is often impractical to implement, simple changes that can reduce exposure to many perennial triggers, such as house dust mites, animal dander, and mold, may assist with symptom control.[1,6]

Dust-mite avoidance (e.g., the use of impermeable covers on box springs, mattresses, and pillows) has traditionally been used as a method of reducing allergen exposure. Although this practice continues to be recommended frequently, it is controversial. Studies have shown less dust-mite levels in mattresses with impermeable covers, but this has not been correlated to improvement in symptoms.[1] Other methods of reducing antigen exposure include washing bedding at least weekly in hot water >130°F (>55°C) and dried under high heat in an electric dryer,[36] removing upholstered furniture, and washing floors daily.[1] Also, reducing humidity in the house to below 50% and replacing carpets with linoleum, tile, or wood floors are commonly recommended.[36]

Mold avoidance is difficult when outdoor humidity levels are high, but covering cold, moist surfaces such as water pipes with insulation and increasing ventilation can help reduce humidity. Also, visible mold should be removed from surfaces with detergent and water and any imbedded mold should also be removed.[36] Because L.B. has recently moved into an older home, he may not have used these avoidance strategies. These should be recommended and explained during the initial clinical consultation.

THERAPEUTIC OBJECTIVES FOR ALLERGIC RHINITIS

CASE 20-1, QUESTION 3: What are the therapeutic objectives in treating L.B.?

The therapeutic objectives for the treatment of allergic rhinitis are to control symptoms and permit all usual daily activities with no adverse effects of therapy. In patients with seasonal exacerbations, another objective is to prevent the onset of symptoms by anticipating the patient's season of sensitivity. In L.B.'s case, he should use environmental measures to reduce exposure and then begin chronic treatment with possible add-on therapy instituted 2 weeks before the start of pollen season.

CHOICE OF THERAPEUTIC AGENT

CASE 20-1, QUESTION 4: L.B. has used diphenhydramine for many years with good symptom relief and, as he recalls, only minimal daytime sedation. He asks your opinion regarding whether this is the best treatment for his allergic symptoms. He specifically requests the most cost-effective treatment available, because he must pay cash out-of-pocket for any medications. What therapy do you recommend and how should it be initiated?

Based on effectiveness and convenience, including nonprescription availability, oral antihistamines are the most frequent initial therapy recommended for patients with allergic rhinitis, particularly those with mild symptoms.[1] They reduce symptoms of nasal itching, sneezing, and rhinorrhea,[3] as well as ocular complaints but offer no benefit for nasal congestion. FGAs (e.g., diphenhydramine, brompheniramine, chlorpheniramine, and clemastine) lack specificity for the H_1 receptor and can cause significant sedation, various anticholinergic side effects, and can impair performance,[29] all of which limit their usefulness. Although at times these effects are considered desirable (e.g., to aid in sleep and dry nasal secretions), the SGAs (e.g., loratadine, fexofenadine, cetirizine, desloratadine, and levocetirizine)[28] are preferable in most instances.[1,2,3,37]

Antihistamines block the effects of histamine by one of two mechanisms: (i) as an H_1-receptor antagonist and (ii) as an inverse agonist of the H_1-receptor.[4] FGAs cross the blood–brain barrier (BBB) leading to unwanted adverse effects. The non-sedating antihistamines (second- and third-generation agents) do not cross the BBB[4] and therefore are less sedating and preferred for small children and the elderly. L.B. has experienced a good response to an FGA without complaints of excessive drowsiness. However, sedation includes both drowsiness (i.e., the subjective state of sleepiness or lethargy) and impairment (i.e., an objective decrease in specific physical or mental abilities),[4] and cognitive impairment can occur[4] even in the absence of overt drowsiness. Although patients can exhibit tolerance to sedative properties of FGAs, they may not perceive the performance impairment that is still present. This has led to a consensus opinion among experts that SGAs are preferred to FGAs when treating allergic rhinitis.[1,3,5,37]

Essentially, all the antihistamines listed in Table 20-2 are equally effective.[2] Therefore, the choice of agent is based on duration of action, side-effect profile (especially drowsiness and anticholinergic effects), risk of drug interactions, and cost.[1] Some patients claim that a kind of "tolerance" to the therapeutic effects occurs with antihistamines, in that with consistent use over time they perceive less symptomatic relief. Although no pharmacologic explanation exists to support these observations, patients may experience benefit from switching therapies if this perception presents.[1]

The major advantages of SGAs are their selectivity to the H_1-receptor and their reduced central nervous system sedative effects.[6,28] Desloratadine, fexofenadine, loratadine, and levocetirizine—at recommended doses—are reported to have no sedating effects.[6] Loratadine and desloratadine can cause sedation at higher than recommended doses.[6] Cetirizine[6] and levocetirizine[1] have more sedation potential than the other second- or third-generation agents.[6] Another advantage of SGAs is that most products can be dosed once daily[6] to improve patient adherence to therapy. Specific antihistamines are compared in Table 20-2. Maximum benefit is seen with continued use of oral antihistamines, but intermittent use may provide relief for many individuals.[1] In the case of L.B., it would be reasonable to begin therapy with loratadine 10 mg daily, because as an SGA it has demonstrated efficacy with minimal side effects and is also available without a prescription (as he requested) and as a generic formulation, which will further control costs.

INTRANASAL ANTIHISTAMINES

CASE 20-1, QUESTION 5: L.B. reports that a friend with similar symptoms had experienced relief from an antihistamine nasal spray. Is it possible to give antihistamines by this route, or is L.B. confusing this with other topical therapies, such as decongestants or corticosteroids? Are intranasal antihistamines appropriate for L.B.?

Topical formulations are available for intranasal use. These are considered to be equal in efficacy to oral SGAs[1,14] with a quicker onset of action.[37] Also, they may improve congestion.[1,6] The intranasal antihistamines (azelastine and olopatadine) have a faster onset of action than oral agents,[1] but unfortunately require twice daily dosing.[6] Early studies showed the side effects of intranasal antihistamines to be comparable to the FGAs in terms of somnolence; however, more recent data show much lower rates (0.4%–3%) similar to those of placebo and intranasal steroid groups.[1] Intranasal azelastine can also cause local side effects, including nasal irritation, dry mouth, sore throat, and mild epistaxis.[29] An objectionable bitter aftertaste is a significant problem, occurring in up to 20% of patients.[29] The original intranasal product (Astelin) was saline-based (and has since been removed from the market); but a newer formulation (Astepro) includes sorbitol and sucralose to mask this bitter taste.[38] Azelastine is also available generically. Patient complaints are fewer with the newer product, but still present.

A potential role for intranasal antihistamines is for patients who do not respond adequately to oral antihistamines.[1] In addition, some patients may prefer the intranasal route of administration or benefit from concomitant therapy with intranasal antihistamines and intranasal corticosteroids. As a prescription-only product, an intranasal antihistamine (even if available generically) would be more expensive than many oral alternatives. Because of the expense associated with prescription-only status, increased risk of side effects, and possibly objectionable taste, topical azelastine is not an optimal therapeutic option for L.B.

Decongestant Therapy

CASE 20-1, QUESTION 6: What role do decongestants have in L.B.'s treatment?

Nasal congestion is often much less severe in patients who experience only intermittent symptoms, but as L.B.'s symptoms have become persistent since his move, the exact frequency and severity of his nasal congestion should be assessed before recommending drug therapy. In patients with only mild, intermittent symptoms, saline irrigation (administered as frequently as needed) is helpful in soothing and moisturizing irritated nasal mucosa but may be impractical. Antihistamines do little to relieve nasal congestion; therefore, patients with moderate to severe congestion may require a combination of an antihistamine with a decongestant. The combination of an antihistamine and an oral decongestant is more effective than either component alone in the treatment of allergic rhinitis.[1]

Both the topical (intranasal) and the oral decongestants are sympathomimetics that directly stimulate α_1-adrenergic receptors, resulting in vasoconstriction.[28] Local effects on the nasal mucosa include reduced turbinate swelling and congestion,[4] and improved nasal airway patency.[1] Oral decongestants include phenylephrine and pseudoephedrine. Until 2005, pseudoephedrine was the more popular agent; however, because of the potential to use it in the manufacturer of illicit substances (e.g., methamphetamine), restrictions on the allowable quantity and methods for purchasing pseudoephedrine-containing products have been implemented at both the state and federal levels. These restrictions have resulted in the reformulation of many oral decongestant products to include phenylephrine as an alternative decongestant. These agents have no effect on sneezing, pruritis, or ocular symptoms.[4] A meta-analysis of phenylephrine used as a decongestant in doses approved for nonprescription use has raised concerns about its efficacy as an oral agent;[39] however, the FDA has determined that there are adequate data to support its continued use. The available oral and topical decongestants, some of which are available without prescription, are compared in Table 20-3.

Oral decongestants can cause systemic side effects, particularly those associated with central nervous system stimulation (e.g., nervousness, insomnia, tremor, anxiety, and panic attacks).[28] Cardiovascular stimulation (e.g., tachycardia, palpitations, increased blood pressure) can also occur, so patients with hypertension should be monitored carefully while taking oral decongestants.[28] Because oral decongestants are not associated with the development of rebound congestion, in most patients they are appropriate for intermittent short-term use; but not chronic use.[24] Topical administration of decongestants generally does not lead to systemic side effects; however, these agents are not appropriate for chronic use in rhinitis because of their potential for causing rebound congestion (see Case 20-7).

Because L.B. is complaining of nasal congestion, he will require a decongestant in addition to the loratadine. He may choose to use a once-daily fixed-dose combination product (e.g., loratadine 10 mg + pseudoephedrine extended-release 240 mg) or to supplement the daily loratadine with pseudoephedrine as needed. Although L.B. has used pseudoephedrine in the past without a problem, he may require education regarding the new procedures for purchasing this product, while assuring him that the new restrictions are not related to the drug's safety as a decongestant. In addition, although his hypertension is controlled, his blood pressure should be monitored regularly to detect any effect. If L.B. is ready to consider a prescription product, an intranasal steroid (discussed subsequently) would also be a reasonable option for him.

Ocular Therapies

RELATIONSHIP BETWEEN OCULAR AND NASAL SYMPTOMS

CASE 20-1, QUESTION 7: L.B.'s new therapies are effective for his persistent nasal symptoms; however, in the spring he complains that his eyes are itchy and watery and that the loratadine and pseudoephedrine do not seem to be helping. How are L.B.'s ocular symptoms related to his allergic rhinitis?

The most common forms of allergic ocular disorders are seasonal (intermittent) allergic conjunctivitis (SAC) and perennial allergic conjunctivitis (PAC).[40] The symptoms of both SAC and PAC are identical in that they are caused by allergic response in the conjunctiva to airborne allergens. SAC symptoms commonly occur in response to airborne pollens, whereas PAC is because of perennial allergens such as house dust mites.[40] The symptoms of allergic conjunctivitis are itchy eyes, redness, and swelling of the conjunctiva.[40]

Because of the potential for long-term damage to vision,[40] persistent ocular conditions should always be assessed by an eye care professional. Other ocular problems that can be confused with allergic conjunctivitis include atopic keratoconjunctivitis and vernal keratoconjunctivitis, and giant papillary conjunctivitis[40] (see Chapter 54, Eye Disorders).

CHOICE OF THERAPEUTIC AGENT

CASE 20-1, QUESTION 8: What are the treatment options for L.B.'s allergic conjunctivitis, and how does the clinician choose between the available options?

Seasonal and perennial allergic conjunctivitis are treated similarly with only the duration of the treatment course differing (i.e., episodic vs. chronic treatment). Nonpharmacologic treatment includes avoidance of aeroallergens to the extent possible, cold compresses,[41] and lubrication with frequent application of artificial tear substitutes to provide a barrier to and dilute various allergens and inflammatory mediators on the ocular surface.[40] The available therapeutic options for management of allergic conjunctivitis include topical ocular administration of antihistamines, decongestants (vasoconstrictors), mast-cell stabilizers, and nonsteroidal anti-inflammatory drugs (Table 20-5).[41] These ocular medications act by the same mechanisms as their nasal counterparts. In addition, topical ophthalmic corticosteroids have a limited role in the acute management of allergic conjunctivitis; however, they are not indicated for prolonged use because of the risk of serious infectious complications in the eye.[40]

In the case of L.B., a trial of antihistamine + vasoconstrictor combination eye drops (e.g., pheniramine maleate 0.3% + naphazoline hydrochloride 0.025%) one to two drops in the affected eye(s) up to 4 times a day for management of acute symptoms is an appropriate recommendation for short-term use. Note that the overuse of ocular vasoconstrictors can lead to rebound conjunctivitis, similar to that occurring with nasal decongestants (see Drug-Induced Nasal Congestion: Rhinitis Medicamentosa section). As a result, the use of a topical ophthalmic decongestant should be limited to 3 to 5 days. If the patient exhibits chronic symptoms, consider a switch to an intranasal corticosteroid (which may have better efficacy for combination symptoms)[1] or refer to specialist care.

Cromolyn Therapy

CASE 20-2

QUESTION 1: J.C. is a 10-year-old girl who has been experiencing rhinorrhea and sneezing during visits to her father's home in another state a couple of times each year. On questioning, J.C.'s mother reveals that although J.C. has not complained of symptoms previously, her father adopted a puppy from the local animal shelter about a year ago and the symptoms correspond to the times that the child spends with the dog. J.C. will be visiting her father again next month, and she is hoping to purchase something without a prescription to prevent her from "getting sick and missing out on her summer vacation." What options are available to treat J.C.'s intermittent symptoms of allergic rhinitis?

These symptoms may reflect mild allergic rhinitis triggered by exposure to animal dander. When it is possible to anticipate symptoms, as in J.C.'s case, initiating prophylactic therapy can help lessen the impact of allergen exposure.[36] Although intermittent use of antihistamines or intranasal corticosteroids are commonly selected options, intranasal cromolyn sodium, administered regularly beginning several weeks before each trip may also offer benefit in this situation. Because the mother indicates that she wants to select an OTC product, allergen avoidance strategies plus cromolyn nasal spray would be a reasonable choice for initial therapy. The drawbacks to this are its out-of-pocket cost, its technique-dependent administration, its multiple daily dosing requirements (up to 6 times daily),[24] and its reduced effectiveness compared with other treatments.[3]

CASE 20-2, QUESTION 2: What strategies should J.C.'s father use to minimize exposure to the allergic triggers?

To minimize J.C.'s exposure to allergens, the dog should be kept out of the child's bedroom at all times and, when possible, kept outside or confined to an uncarpeted area of the home. J.C.'s father should use a high-quality air purifier[42] and should vacuum the home with a double-filter system while J.C. is out of the house. Although evidence of benefit is unclear, it may be helpful to wash the dog at least twice a week while the child visits.[1] Similarly, after touching or playing with the dog, J.C. should wash her hands especially before touching her face.[42] The additional expense of regular, commercial cleaning of air ducts is not cost justified.

INSTRUCTIONS FOR USE

CASE 20-2, QUESTION 3: How should J.C. be advised to use cromolyn nasal spray to prevent her symptoms?

To be effective, cromolyn nasal spray must be dosed several times each day, which can hinder adherence.[37] The initial dose for the cromolyn sodium nasal spray (5.2 mg/actuation) is one spray in each nostril 3 to 4 times a day up to 6 times daily.[29] In some patients, symptom control can be maintained with dosing 2 to 3 times per day. J.C. should be instructed to begin therapy at least 2 weeks before her planned visit because of the delay in the onset of action for this agent.

Table 20-5

Topical Ophthalmic Medications Commonly Used for Allergic Conjunctivitis

Generic Name (Example Brand Product)	Available Dosage Forms/Strength	Dose
Antihistamines		
Azelastine (Optivar)	Ophthalmic solution: 0.05%	Adults and children ≥3 years: 1 drop in the affected eye(s) every 12 hours
Emedastine (Emadine)	Ophthalmic solution: 0.05%	Adults and children ≥3 years: 1 drop in the affected eye(s) up to 4 times daily
Epinastine (Elestat)	Ophthalmic solution: 0.05%	Adults and children ≥3 years: 1 drop in the affected eye(s) twice daily
Antihistamine/Decongestant Combinations		
Pheniramine + Naphazoline (Naphcon-A, Opcon-A, Visine-A)[a]	Ophthalmic solution: naphazoline HCl 0.025% + pheniramine maleate 0.3%	Adults and children ≥6 years: 1–2 drops in the affected eye(s) every 6 hours for up to 3 days
Antihistamine/Mast-Cell Stabilizers		
Ketotifen (various brand names)[a]	Ophthalmic solution: 0.025%	Adults and children ≥3 years: 1 drop in the affected eye(s) every 8–12 hours
Olopatadine (Pataday, Patanol, Pazeo)	Ophthalmic solution: 0.1%, 0.2%, 0.7%	0.1%: Adults and children ≥3 years 1 drop in affected eye(s) twice daily at an interval of 6–8 hours. 0.2% and 0.7%: Adults and children ≥2 years: 1 drop in the affected eye(s) once daily
Alcaftadine (Lastacaft)	Ophthalmic solution: 0.25%	Adults and children ≥2 years: 1 drop in the affected eyes(s) twice daily
Bepotastine (Bepreve)	Ophthalmic solution: 1.5%	Adults and children ≥2 years: 1 drop in the affected eyes(s) twice daily
Mast-Cell Stabilizers		
Cromolyn Sodium (Crolom)	Ophthalmic solution: 4%	Adults and children ≥4 years: 1–2 drops in the affected eye(s) 4–6 times daily
Lodoxamide (Alomide)	Ophthalmic solution: 0.1%	Adults and children ≥2 years: 1–2 drops in affected eye(s) 4 times daily for up to 3 months

Nedocromil (Alocril)	Ophthalmic solution: 2%	Adults and children ≥3 years: 1–2 drops in the affected eye(s) every 12 hours
Nonsteroidal Anti-Inflammatory Drugs[b]		
Ketorolac (Acular)	Ophthalmic solution: 0.5%	Adults and children ≥3 years: 1 drop in the affected eye(s) 4 times daily
Corticosteroids[c]		
Loteprednol (Alrex)	Ophthalmic suspension: 0.2%	Adults: 1 drop in the affected eye(s) 4 times daily

[a] Available without a prescription.

[b] Other ophthalmic nonsteroidal anti-inflammatory drugs (diclofenac, flurbiprofen, suprofen) indicated for intraoperative miosis and for postcataract surgery, but not approved for allergic conjunctivitis.

[c] Other ophthalmic corticosteroids (dexamethasone, difluprednate, triamcinolone, fluorometholone) indicated for ocular inflammation, but not approved for allergic conjunctivitis.

Source: Facts & Comparisons eAnswers. http://online.factsandcomparisons.com/index.aspx? Accessed May 8, 2015.

The clinician should ensure that both parent and child can demonstrate appropriate administration technique before therapy is initiated. On first use, the device should be primed until a consistent fine mist spray is achieved. J.C. should be instructed to gently blow her nose and then spray the cromolyn sodium solution into each nostril in a slightly upward direction, parallel to the nasal septum.

Topical nasal cromolyn has an excellent safety profile, including minimal incidence of adverse effects. Local irritation with burning, stinging, and sneezing being the most common manifestations. The safety of cromolyn[6,24] has made it widely used as initial therapy for children with allergic rhinitis and for treating rhinitis during pregnancy. Table 20-6 includes information about intranasal cromolyn dosing and availability.

Intranasal Corticosteroid Therapy

CASE 20-3

QUESTION 1: A.R. is an 8-year-old girl with allergic rhinitis and asthma. She has been treated with orally inhaled budesonide for asthma and oral loratadine for rhinitis. Her mother reports that she frequently sneezes, complains of an itchy nose and eyes, and does not sleep well at night because of nasal congestion. She also reports that she cannot give her cetirizine on a daily basis because it “makes her drowsy at school.” Her asthma has been well controlled in the past; however, she is concerned that she is experiencing some shortness of breath and that this might be related to her allergies. While you are talking to her, you note that A.R. breathes exclusively through her mouth, sniffs frequently, and rubs her nose. You also notice dark circles under her eyes. What signs and symptoms of allergic rhinitis is A.R. displaying?

Table 20-6

Additional Oral and Intranasal Agents for Rhinitis

Generic (Brand Product)	Available Dosage Forms/Strength	Adult Dose	Pediatric Dose
Oral			
Leukotriene modifiers Montelukast (Singulair)	Tablets: 10 mg Tablets, chewable: 4 mg, 5 mg Oral granules: 4 mg	10 mg once daily	Children 6–14 years: 5 mg once daily Children 2–5 years: 4 mg once daily Children 6–23 months: 4 mg once daily
Intranasal			
Antihistamine Azelastine (Astepro)	Nasal spray: 0.1% 0.15%	Perennial: 0.15%: 2 sprays/nostril twice daily Seasonal: 0.1%: 1–2 sprays/nostril twice daily 0.15%: 1–2 sprays/nostril twice daily or 2 sprays/nostril once daily.	Perennial: Children 6 months–5 years (0.1%) 1 sp EN BID Children ≥2 years: 0.15%: 2 sprays/nostril twice daily Children 6–11 years: 0.1% or 0.15%: 1 spray/nostril twice daily Seasonal: Children 6–11 years: 0.1% or 0.15%: 1 spray/nostril twice daily Children 2–5 years: 0.1%: 1 spray/nostril twice daily
Olopatadine (Patanase)	Nasal Solution: 0.6%	Two sprays per nostril twice daily	6–11 years: 1 spray per nostril twice daily
Mast-cell stabilizer Cromolyn sodium (Nasalcrom)[a]	Nasal spray: 5.2 mg/spray	1 spray/nostril 3–4 times/day (every 4–6 hours; max 6 times daily)	Children ≥2 years: 1 spray/nostril 3–4 times/day (every 4–6 hours; max 6 times daily)
Anticholinergic Ipratropium bromide (Atrovent)[b]	Nasal spray: 21 mcg/spray (for perennial symptoms), 42 mcg/spray (for seasonal symptoms)	2 sprays/nostril up to 4 times daily (max = 672 mcg/day)	Children ≥6 years: 42 mcg/spray: 2 sprays/nostril 2–3 times/day Children 5–11 years: 84 mcg/spray: 2 sprays/nostril 3 times daily

[a] Available without a prescription.

[b] Optimum dosage varies with the response of the individual patient. It is always desirable to titrate an individual to the minimum effective dose to reduce the risk of side effects. In addition, the safety and efficacy of the use of ipratropium 42 mcg nasal spray beyond 3 weeks in patients with seasonal allergic rhinitis has not been established.

Source: Facts & Comparisons eAnswers. http://online.factsandcomparisons.com/index.aspx? Accessed May 8, 2015.

A.R. is showing the classic signs of allergic airways disease in children. She is sniffing and snorting in response to nasal itching and discharge. The frequent upward rubbing of the nose (generally with the palm of the hand) is known as the "allergic salute"[1] and is caused by nasal itching. Long-standing symptoms can lead to facial abnormalities, including the formation of a transverse crease across the bridge of the nose.[3] Dark circles under the eyes are commonly known as "allergic shiners" and they can be further aggravated by the frequent rubbing of the eyes associated with severe ocular itching.[1,37]

CASE 20-3, QUESTION 2: Given her concomitant asthma, are there any special considerations for treating A.R.'s allergic rhinitis?

Based on the relationship between inflammation in the upper and lower airways, and the similar immunologic mechanisms involved in allergic rhinitis and asthma, it is a reasonable assumption that poor control of upper airway allergies can have a negative impact on asthma control.[24] In fact, rhinitis is a risk factor for asthma development,[37] and poorly controlled rhinitis can aggravate asthma control.[4] In a patient with asthma, like A.R., treatment of allergic rhinitis can also reduce airway hyperresponsiveness and symptoms of asthma.[1,37] Historically, the use of antihistamines (FGAs) was considered problematic for patients with asthma because of a theoretic concern about excessive drying of airway secretions caused by the anticholinergic properties of these agents. It is now clear that most patients with asthma can take any of the antihistamines without adverse pulmonary effects. Oral antihistamines (SGAs) would currently be a logical first addition to an asthma regimen because of their convenient dosing, but A.R.'s experience with these agents in the past has not been positive. For this reason, intranasal corticosteroids should be considered for A.R.

ROLE IN THERAPY

CASE 20-3, QUESTION 3: What would be the role of intranasal corticosteroids in A.R.?

Based on the frequency and severity of symptoms, and the lack of control/side effects with oral antihistamine therapy, intranasal corticosteroids are an appropriate consideration for A.R. Intranasal corticosteroids are the most effective therapy available for the treatment of allergic rhinitis. They are safe, well tolerated, and are highly effective in reducing itching, sneezing, rhinorrhea, and congestion in both adults and children.[1] In addition to improving all nasal symptoms, evidence also suggests that intranasal administration of corticosteroids effectively relieves ocular symptoms.[37] These agents also have demonstrated efficacy for nonallergic rhinitis,[6] rhinitis medicamentosa,[43] and nasal polyps.[44] The currently available intranasal corticosteroids are listed in Table 20-7.

Table 20-7

Intranasal Corticosteroids[a] Commonly Used for Rhinitis

Generic Name (Example Brand Product)	Available Dosage Forms/Strengths	Adult Dosea	Pediatric Dosea
Beclomethasone dipropionate (Beconase AQ) QNasal (HFA) QNasal (Children's)	42 mcg/spray 80 mcg/spray 40 mcg/spray	42 mcg: 1–2 sprays/nostril twice daily 80 mcg: 2 sprays/nostril once daily	Children 6–12 years: 42 mcg: 1 spray/nostril twice daily (max 2 sprays/nostril daily) Children 4–11 years: 40 mcg: 1 spray/nostril once daily (max 2 sprays/nostril daily)
Budesonide (Rhinocort Aqua) (Rhinocort Allergy) (Children's Rhinocort)	32 mcg/spray	1 spray/nostril once daily (max 4 sprays/nostril daily)	Children 6–12 years: 1 spray/nostril once daily (max 2 sprays/nostril daily)
Ciclesonide (Omnaris) Zetonna (HFA)	50 mcg/spray 37 mcg/spray	50 mcg: 2 sprays/nostril once daily 37 mcg: 1 spray/nostril once daily	50 mcg: Children 6–12 years: 2 sprays/nostril once daily (approved for seasonal symptoms in ages >6, and for perennial symptoms for ages >12) 37 mcg: do not use in children <12.
Fluticasone propionate (Flonase Allergy Relief) (Clarispray) (Children's Flonase) (GoodSense Nasoflow) (Ticaspray)	50 mcg/spray	2 sprays/nostril once daily or 1 spray/nostril twice daily	Children 4–11 years: 1 spray/nostril once daily (max 2 sprays/nostril daily)
Fluticasone furoate (Flonase Sensimist)	27.5 mcg/spray	2 sprays/nostril once daily	Children 2–11 years: 1 spray/nostril once daily (max 2 sprays/nostril daily)
Flunisolide (no brand product available)	0.025%	>15 years: 2 sprays/nostril 2 or 3 times daily (max 8 sprays/nostril daily)	Children 6–14 years: 1 spray/nostril 3 times daily or 2 sprays/nostril twice daily (max 4 sprays/nostril daily)
Mometasone furoate (Nasonex)	50 mcg/spray	2 sprays/nostril once daily	Children 2–11 years: 1 spray/nostril once daily
Triamcinolone acetonide (Nasacort AQ) (Nasacort Allergy)	55 mcg/spray	2 sprays/nostril once daily	Children 2–5 years: 1 spray/nostril once daily (max 1 spray/nostril daily) Children 6–11 years: 1–2 sprays/nostril once daily (max 2 sprays/nostril daily)
Azelastine HCl/fluticasone	137/50 mcg/spray	1 spray/nostril twice daily	Children ≥6 years: 1

propionate (Dymista)			spray/nostril twice daily

[a] It is always desirable to titrate an individual patient to the minimum effective steroid dose to reduce the risk of side effects. When the maximum benefit has been achieved and symptoms have been controlled, reducing the steroid dose might be effective in maintaining control of rhinitis symptoms.

Source: Facts & Comparisons eAnswers. http://online.factsandcomparisons.com/index.aspx? Accessed May 11, 2015.

Intranasal corticosteroids are the most effective agents available over other therapeutic options. They are frequently rated as more effective than antihistamines,[1] although the benefit from therapy requires correct use of the administration device.[3] Intranasal corticosteroids improve congestion, sneezing, rhinorrhea, and itching[36] with no difference in efficacy amongst the available options.[1]

MECHANISM OF ACTION

CASE 20-3, QUESTION 4: How do intranasal corticosteroids work to reduce the symptoms of allergic rhinitis?

Corticosteroids interact with a specific steroid receptor in the cytoplasm of a cell, and the steroid receptor complex then moves into the cell nucleus where it influences protein synthesis and inhibits the breakdown of phospholipids to arachidonic acid[45]; this, in turn, inhibits the formation of prostaglandins and leukotrienes. Topical corticosteroids reduce the number of eosinophils, basophils, and mast cells in the nasal mucosa and epithelium; directly inhibit the release of mediators from mast cells and basophils; reduce mucosal edema and vasodilation; and stabilize the endothelium and epithelium, resulting in decreased exudation.[1] Topical corticosteroids inhibit both the early-phase and late-phase reactions to antigen challenge,[28] and therefore pretreatment and continued use are recommended.[1]

CHOICE OF THERAPEUTIC AGENT

CASE 20-3, QUESTION 5: What intranasal corticosteroid products are appropriate to manage A.R.'s allergic rhinitis?

Currently marketed intranasal corticosteroid products vary in the pharmacologic characteristics that can influence patient acceptance and adherence; however, there do not appear to be significant advantages with regard to efficacy among them.[1] Primary differences among products include potency, dosing regimens, delivery systems, spray volume,[29] and patient preference. For sensitive patients, there may be some theoretical advantage to products that are preservative or alcohol-free.

The ideal intranasal corticosteroid agent should exhibit high topical potency and low systemic activity. After topical administration, the corticosteroid may reach the systemic circulation by absorption across the nasal mucosa or through gastrointestinal absorption of the swallowed portion of the dose.[44] Studies have shown that varying sensory attributes (e.g., aftertaste, nose runout, and smell) affect acceptability of, and preference for, particular nasal corticosteroid products.[1] Some degree of experimentation may be required to find the optimal product for A.R.

SAFETY

CASE 20-3, QUESTION 6: How safe are intranasal corticosteroids in this situation?

The corticosteroids currently available for intranasal administration are listed in Table 20-7. Among available products, intranasal corticosteroids have similar efficacy in clinical trials.[1] Budesonide, beclomethasone, ciclesonide, and flunisolide are indicated for ages 6 years or older. Beclomethasone HFA and fluticasone propionate are labeled for ages 4 and up, and mometasone and fluticasone furoate are indicated in children 2 years and older.[29] Triamcinolone (Nasacort Allergy 24 hour) and Fluticasone (Flonase Allergy Relief) are available OTC and approved in patients 2 and 4 years and older respectively. Because A.R. is 8 years old, theoretically she is a candidate for an OTC intranasal steroid; however, given her concomitant asthma, a prescription agent may be a better choice. Because poor control of upper airway allergies can have a negative impact on asthma control,[24] proper monitoring by her provider is important.

A common concern regarding the use of corticosteroids in children is the risk of growth suppression. Current US FDA labeling for inhaled and intranasal corticosteroid preparations include wording that use of these products in children may reduce their rate of growth. Although beclomethasone may be associated with reduced growth velocity,[44] numerous studies have shown no growth delay in children treated long term with newer intranasal steroids.[1] Specifically, studies with mometasone, fluticasone, budesonide, ciclesonide, and triamcinolone have shown no effect on growth at recommended doses for up to 1 year.[44] It is always judicious to recommended and utilize the lowest effective dose of intranasal corticosteroids especially in a pediatric population also on a concomitant inhaled corticosteroid agent. Because A.R. has concomitant asthma, this may be the case in this patient.

Other potential adverse effects of chronic intranasal corticosteroids have been investigated. Severe local effects such as nasal mucosal atrophy or septal ulceration are rarely seen and can be prevented with appropriate technique.[44] Changes in bone mineral density, intraocular pressure, or cataracts do not appear to be of a concern.[44]

INSTRUCTIONS FOR USE

CASE 20-3, QUESTION 7: A.R. is given a prescription for budesonide, two actuations in each nostril twice daily. How should she be counseled to use this drug?

Although intranasal corticosteroids have an excellent safety profile, some local adverse effects can occur. The currently available products are all aqueous solutions delivered via a manual spray pump; these are much less drying than the original propellant-based aerosol formulations of the same products. The most commonly reported side effect is epistaxis.[44] Local irritation, burning, stinging, and dryness are also possible.[1] Proper technique in using the nasal corticosteroid products can reduce the risks for these side effects.[1,6]

Patient education is important to ensure proper use of, and response to, the intranasal corticosteroids.[28] A.R. should be instructed to blow her nose gently before using the nasal spray as severe blockage of the nasal passage may prevent deposition of the drug at the intended site of action. The patient should be instructed to direct the spray away from the nasal septum.[36] This technique is facilitated by using the contralateral hand during administration to each nostril. This results in pointing the applicator nozzle straight and back to ensure application is parallel to the septum.[3]

Therapeutic benefit to intranasal steroids is generally evident in a few days,[37] although some newer agents may begin to relieve symptoms within hours because of a quick onset of effect.[1] Fluticasone has been effective when used on an as-needed basis.[1] Nonetheless, it is reasonable to advise patients that full benefit may not be realized for up to 2 to 3 weeks.[3]

Systemic Corticosteroids

CASE 20-3, QUESTION 8: What is the role of systemic corticosteroid therapy in the management of A.R.'s allergic rhinitis?

In contrast to the minimal side effects of the topical corticosteroids, systemic administration of these drugs can cause numerous, and at times serious, side effects. Systemic administration, therefore, must be reserved for only short-term, adjunctive therapy in cases of severe, debilitating rhinitis. In such cases, a short course of relatively high-dose corticosteroid, so-called burst therapy, can be administered. Prednisone 40 mg/day for adults or 1 to 2 mg/kg/day for children (or an equivalent dose of a comparable compound) every morning for up to 7 days effectively relieves acute, severe rhinitis symptoms. If A.R. were to have a particularly severe exacerbation of her allergic rhinitis such that it interfered with sleep or ability to attend school, an oral corticosteroid burst would be indicated. More likely, A.R. would require a short course of systemic corticosteroids for an acute asthma exacerbation, which should also result in improved nasal symptoms.

Combination Therapy

CASE 20-3, QUESTION 9: Would there be an advantage in combining various therapies for allergic rhinitis in A.R.?

The rationale for combining agents to treat allergic rhinitis is based on the theoretic benefit of additive or synergistic reactions. Various combinations have been studied. Concomitant use of antihistamines and decongestants has been shown to relieve individual nasal symptoms compared with either agent alone. Combining intranasal antihistamines and corticosteroids also is beneficial.[1] However, the combination of intranasal corticosteroids with oral antihistamines has not been shown to offer clinical benefit over use of intranasal steroids alone.[1] Similarly, the combination of oral antihistamines and leukotriene modifier therapy is generally not recommended.[1] When combination therapy of any kind is used, once symptoms are controlled, one agent should undergo a trial for discontinuation.

Leukotriene-Modifying Agent Therapy

CASE 20-4

QUESTION 1: K.H. is a 58-year-old man with allergic rhinitis. He has experienced symptoms during ragweed pollen season for several years. He has used various antihistamines for his symptoms during this time with moderate success. At times, K.H. has self-medicated with nonprescription medications, including clemastine and diphenhydramine. This year, he initiated therapy with diphenhydramine 1 week before the pollen season, but began experiencing symptoms of urinary retention after 10 days. His physician advised him that this might be related to the antihistamine aggravating his enlarged prostate and he was advised to use fexofenadine 60 mg twice daily.

After 1 week, K.H. complains that the medication is not working. After seeing an advertisement on television, he inquires about the use of a leukotriene modifier for his allergic rhinitis. What is the mechanism for the K.H.'s urinary discomfort attributed to the diphenhydramine?

K.H. is exhibiting symptoms of urinary outflow obstruction or prostatism. Common features of this are frequency, hesitancy, slow urine stream, dribbling, and bladder fullness after voiding. The most common cause of obstruction is benign prostatic hyperplasia (BPH). Because the prostate is located anatomically around the urethra, enlargement of the gland can obstruct urine flow.[46]

The bladder and urethra are made up of smooth muscle tissue that is innervated by the sympathetic and parasympathetic divisions of the autonomic nervous system. The detrusor musculature is predominantly innervated by β-adrenergic and cholinergic receptors, whereas the bladder neck (or outlet) is innervated predominately by α-adrenergic receptors.[47] Sympathetic stimulation causes relaxation of the detrusor muscle to allow bladder filling, closure of the urethra, and decreased bladder emptying. Cholinergic stimulation of the detrusor causes contraction of the detrusor to cause bladder emptying. Initially, the detrusor musculature can compensate for the urethral obstruction in BPH. Eventually, however, the detrusor muscle fibers hypertrophy and decompensate, resulting in urinary retention and detrusor hyperreflexia manifesting as urinary frequency, urgency, urge incontinence, and nocturia.[48]

When K.H. took diphenhydramine, the anticholinergic properties of the drug blocked detrusor contraction and precipitated acute urinary retention.[47] In this case, therapy with a SGA (i.e., fexofenadine) is more appropriate because these agents have little to no anticholinergic side effects.

EFFICACY

CASE 20-4, QUESTION 2: What is the rationale and evidence that a leukotriene modifier might be beneficial in the management of K.H.'s allergic rhinitis?

Leukotrienes are important inflammatory mediators in the upper and lower airways and are present in nasal secretions of patients with allergic rhinitis. They serve as inflammatory mediators that attract eosinophils, increase microvascular leakage, edema, and mucus gland secretion.[4] These actions lead to the symptoms of allergic rhinitis, as well as those of asthma.[24] In clinical trials, leukotriene modifiers relieve nasal symptoms in patients with allergic rhinitis however not as well as nasal corticosteroids.[1]

In actual use, the benefit of leukotriene modifiers has been modest; therefore, their role is typically adjunctive to the use of first-line agents for allergic rhinitis.[1] Clinical decisions about the value of combining treatments should be based on the specific clinical situation. Because K.H. has experienced intolerance to FGAs and a lack of efficacy with SGAs, a trial with an intranasal corticosteroid or a leukotriene-modifying agent is appropriate. Specifically, a patient with mild asthma and allergic rhinitis may benefit from therapy with a leukotriene modifier with or without an antihistamine.[28] If used, however, a risk exists of a rare complication known as Churg–Strauss syndrome, which is characterized by eosinophilia, vasculitic rash, worsening pulmonary symptoms, cardiac complications, and neuropathy.[49] Table 20-6 includes information about the use and availability of montelukast, which is currently the only leukotriene modifier approved for allergic rhinitis.

Complementary and Alternative Therapies

CASE 20-5

QUESTION 1: C.L., a 25-year-old woman, presents in mid-August complaining that her allergies are worsening daily. Symptoms are nasal discharge and obstruction, repetitive sneezing, and itching of the nose, eyes, and throat. She is fatigued and has difficulty concentrating. Her symptoms have been occurring in late spring and summer since high school, and she has used a variety of medications intermittently (clemastine, fexofenadine, beclomethasone nasal, ketotifen ophthalmic) over the years. C.L. is a competitive runner but has been unable to run as far or as often as usual because of bothersome symptoms. She is also reluctant to use medications as they may be prohibited by her race sponsors. A running partner mentioned that she could control her allergy symptoms with diet, exercise, and herbal remedies purchased at a local nutritional supplement shop. What, if any, alternative treatments have been shown to be efficacious in allergic rhinitis?

Alternative treatments such as yoga, massage, acupuncture, homeopathy, and herbal therapy are common among adults with rhinitis and should be taken into account by health care providers. Literature indicates that 25% to 50% of the general population and up to 70% of children have used an alternative method at least once.[50] A study in Americans showed that 29% had tried alternative treatments for rhinosinusitis.[50] Still, because allergic rhinitis is largely a self-managed disease, it is likely that reported use of these agents is underestimated. A survey found that only 43% of subject who had used alternative methods had informed their provider about it.[50] For these reasons, patients should always be questioned specifically about the use of alternative therapies during the patient interview. Although some alternative approaches such as acupuncture have been deemed to be safe,[1,51] the safety and efficacy of herbal remedies has not been clearly established and cannot be recommended at this time.[1] In addition, some complementary therapies have been associated with side effects and potential drug interactions.[50] Because of C.L.'s reluctance to use medications, other strategies are appropriate to consider to help manage her rhinitis symptoms.

PHYSICAL TECHNIQUES

Camphor and menthol-delivered rubs (Vicks VapoRub, Breathe Right Colds Nasal Strips) have been shown to have an ameliorating effect on nasal congestion;[52] however, the effects are short-lived.[29] Other forms of aromatherapy suggested to relieve nasal congestion are lacking data related to efficacy.[52] Saline nasal irrigation (e.g., neti pot) is simple, inexpensive, and has been shown to have some efficacy.[53]

HERBAL MEDICINES

It has been suggested that some herbs have antiallergy, anti-inflammatory, and improved immune system effects that may be helpful to ease symptoms of allergy.[51,54] With this in mind, echinacea has become one of the top-selling herbal products in the United States. Echinacea, also known as the purple cornflower, however, is a member of the daisy Compositae (Asteraceae) family.[55] Although Echinacea is often used for immune-related disorders, patients with known allergy to these plants should be cautioned regarding the use of Echinacea products.

A few herbal therapies, including butterbur, biminne, Chinese herbal mixture,[1] and spirulina[50] potentially hold some promise because of positive results in trials on clinical symptoms and quality of life in patients with AR, but more investigation is needed before they can be included in recommended treatment algorithms.[1] No good clinical data are available on the efficacy of supplements containing grapeseed extract, honey, lemon peel, stinging nettle, or red onions.[50]

OTHER

Reports regarding the use of intranasal zinc for upper respiratory symptoms, particularly those associated with the common cold, and congestion associated with allergies have been conflicting. Although zinc gels and sprays are popular OTC products, studies show inconsistent results[56] and may be associated in zinc-induced anosmia syndrome.[56] Some products have been removed from the market because of this problem. By giving patients minuscule amounts of allergen, homeopathic medicines are designed to mimic and augment a patient's own immune responses and natural defenses.[57] Some studies have shown that patients with allergic rhinitis who received homeopathic dilutions of allergens had significantly better nose running scores than those in the placebo group.[57] Further investigation is needed before homeopathy can be recommended for allergic rhinitis.

Although a variety of alternative remedies are widely available and used frequently in self-treatment, based on evaluation of these data, there is no firm recommendation for C.L. regarding the use of alternative therapies in allergic rhinitis.[1] C.L. should be advised to consult with the specific regulating agency that governs her sporting activities (e.g., the World Anti-Doping Agency for Olympic events) to gain a clear understanding of medicines that are banned in all cases as compared to those that may be used with medical exemptions or used outside of the competitive window. This may allow her to use many conventional treatments (e.g., intransal steroids) with confidence. Saline irrigation would also be a safe, noncontroversial option that may offer some efficacy.

Immunotherapy

EFFICACY

CASE 20-6

QUESTION 1: R.C. is a 25-year-old schoolteacher who has experienced allergic symptoms since childhood, but noticed a worsening after she graduated from college and moved to a new area of the country. Although she has mild symptoms year-round, she has severe exacerbations during April through June and August through October each year. During these periods, she feels that exposure to cut grass and weeds provoke profound nasal symptoms. She also notes that when she spends more time outdoors in spring and early fall, her regular therapy that she buys OTC, fluticasone (Flonase) nasal spray (two sprays per nostril once daily), is less effective. She has added loratadine (10 mg daily) during this time, but is frustrated by having to take so many medications while continuing to experience symptoms. R.C. asks your opinion about allergy shots, remarking that she started them as a child with some relief, but moved after a year and never resumed treatment. Is allergen immunotherapy effective for reducing symptoms of allergic rhinitis?

Allergen-specific immunotherapy has long-term efficacy, induces clinical and immunologic tolerance, and may prevent progression of allergic disease.[58,59] Immunotherapy is available via SCIT (sometimes called “allergy shots”),[58] sublingual aqueous drops[58] not FDA approved in the United States),[1] or sublingual tablets (SLIT).[60] Immunotherapy is unique and capable of changing the course of the disease.[1] By giving dilute solutions of allergen-containing extracts in repeated and increasing doses, immunologic tolerance is provided.[59] Therefore, subsequent exposure to those allergens elicits no or mild symptoms.

Immunotherapy administered via SCIT has been used empirically since the early 1900s, and its efficacy has been documented in many controlled trials.[61] SIT is effective in the treatment of allergic rhinitis and may even prevent the onset of asthma.[1] In addition, the benefit of immunotherapy is long-lived. Even after discontinuation, studies show continued beneficial effects up to 10 years later.[1] SCIT and SLIT should be considered a supplement to drug therapy in specific patients and possibly be used earlier in the course of allergic disease to achieve maximal benefit.[1,60]

ALLERGEN TESTING

CASE 20-6, QUESTION 2: How can the clinician determine R.C.’s specific sensitivities?

Skin testing using the modified prick test method or a prick-puncture method is used to confirm the diagnosis of allergic rhinitis and to determine specific allergen sensitivities. Skin testing is a highly sensitive and a relatively inexpensive objective measurement of allergen sensitivity. Small quantities of allergen are introduced into the skin by pricking or puncturing the skin in the immediate presence of the diluted allergen extract. Fifteen to 35 tests are placed on the upper portion of the back or the palmar surface of the forearms. A positive skin test produces a wheal-and-flare reaction at the site within 10 to 20 minutes of application and should be read after 15 minutes.[62] An experienced clinician, usually an allergist, should conduct skin testing using high-quality allergen extracts and should interpret the results.[62]

The allergens tested vary with geographic location, emphasizing the most common offending plant species that generate airborne particles. Pollen, the primary particle, is produced by trees, grasses, and weeds. Each of these plant groups generally pollinate at about the same time each year: trees in the spring, grasses from early to midsummer, and weeds from late summer into fall before the first killing frost. The onset and potency of the pollen season varies with geographic location and weather, particularly with respect to temperature and moisture. Seasonality can be misleading, however, because settled pollen particles from a previous season may be resuspended in the air following the spring snow melt or periods of heavy winds.

Mold spores are also common airborne allergens. The outdoor molds release their spores from early spring through late fall. Within this long season, spore counts increase and decrease, depending on the presence of local flora on which these molds grow (e.g., grain and other crops, forests, and orchards). Some perennial allergens (e.g., house dust mites, insect and animal dander, and some indoor molds) occur consistently across all geographic distributions.

In addition to skin-prick testing, clinicians can detect allergen-specific IgE antibodies in the blood.[63] Results are reported quantitatively and total serum IgE can be useful in determining if atopy is present.[63] In each case, skin test results[62] or IgE serum levels[63] must be correlated with the patient's clinical history. R.C.'s perennial symptoms with seasonal exacerbations indicate sensitivity to the common perennial allergens with a particular sensitivity to seasonal allergens such as tree, grass, and weed pollen, but these subjective relationships should be confirmed with skin testing.

CASE 20-6, QUESTION 3: R.C. is currently using medications (fluticasone nasal spray and loratadine) for her symptoms. Should these be discontinued before skin testing?

Antihistamines blunt the wheal-and-flare reaction by blocking the effects of histamine on capillaries. Different antihistamines vary in the extent to which they can inhibit wheal formation and in the duration of the inhibitory effect with older first-generation agents being the worst offenders.[62] Other agents that may interfere with skin-prick testing include long-term systemic corticosteroids, topical corticosteroids, tricyclic antidepressants, phenothiazine-type antipsychotics, and antiemetics.[62] Depending on the agent selected, antihistamines must be discontinued from 24 hours to 10 days before skin testing,[62] and even then considerable interpatient variability exists in blocking effects. For best results, R.C.'s loratadine should be discontinued 10 days before her skin testing. Recommendations for discontinuing antihistamines before allergen skin testing are listed in Table 20-8.

Table 20-8

General Recommendations for Discontinuation of Antihistamines Before Allergen Skin Testing

1. Remind patient that allergic symptoms may return during the antihistamine-free period, but that reliable skin tests cannot be performed in a patient taking antihistamines.
2. Discontinue any short-acting antihistamine (i.e., those in Table 20-2 with a duration of suppression ≤4 days) 4 days before skin testing.
3. Discontinue longer-acting antihistamines (i.e., those in Table 20-2 with a duration of suppression >4 days) at a interval appropriate to their duration of effect (e.g., hydroxyzine should be discontinued 10 days before skin testing).
4. Before applying the full battery of skin tests, apply histamine (positive) control and glycerinated diluent (negative) control tests. Application of a 1 mg/mL histamine base equivalent should yield wheal-and-flare diameters of 2–7 mm and 4.5–32.5 mm, respectively, to be considered a normal histamine reaction. A normal cutaneous reaction to histamine control suggests that accurate skin testing can be performed.

From Bousquet J et al. Allergic rhinitis and its impact on asthma (ARIA) 2008 update (in collaboration with the World Health Organization, GA[2]LEN and AllerGen). Allergy. 2008;63(Suppl 86):8.

Other allergy medications, including cromolyn and nasal corticosteroids, have no effect on skin tests. Likewise, most asthma medications, including leukotriene modifiers, inhaled β_2-agonists, cromolyn, theophylline, and inhaled and short-course systemic (burst) corticosteroids have no effect on skin tests.[62] R.C. can continue the use of fluticasone nasal spray, although she waits to be skin tested.

CASE 20-6, QUESTION 4: Is R.C. a candidate for immunotherapy injections and/or sublingual tablets?

Immunotherapy via SCIT or SLIT should be offered to patients who have an inadequate response with pharmacologic treatment for AR with or without environmental controls.[1] Further considerations are the patient's preference, adherence, response to avoidance measures, adverse drug effects, and coexistence of allergic asthma.[1] It has also been shown that the clinical benefits of immunotherapy are similar if not better than standard therapy with intranasal steroids, montelukast, or antihistamines.[60] In the case of R.C., she has year-round symptoms with seasonal exacerbations, she has not experienced symptom relief when using appropriate therapies, and she is motivated to try immunotherapy. In addition, a previous trial in childhood was beneficial. For these reasons, skin-prick testing and a trial of immunotherapy with specific allergens are reasonable.

LENGTH OF THERAPY

CASE 20-6, QUESTION 5: If R.C. decides to proceed with immunotherapy, how long should her therapy continue and how long will the effects last?

After identifying the offending allergens via skin testing, subcutaneous immunotherapy is generally administered in two phases. During the build-up phase, increasing doses of allergen are given once or twice a week until a predetermined target or maintenance dose is achieved. Once this maintenance dose is reached, shots are usually administered every 2 to 3 weeks for the ensuing several years of treatment. Clinical improvement with immunotherapy usually occurs in the first year. In a small percentage of patients, there is no improvement and immunotherapy is discontinued. If symptoms are reduced, however, injections are usually continued for 3 to 5 years of maintenance therapy.[64]

Although immunotherapy can lead to long-term remission of symptoms, one drawback is the lengthy treatment period. SCIT alters the natural course of disease and evidence suggests that efficacy persists long after therapy ends.[1,64]

Immunotherapy via sublingual tablet involves placing the tablet under the tongue for 1 to 2 minutes before swallowing. There is no titration schedule. See Table 20-4 for dosing information and when best to initiate therapy in relation to the allergen season. A benefit of the sublingual tablet form of immunotherapy is only the first dose needs to be administered in the providers office, compared to every dose with

SCIT.[64] Patients, however, need to be adherent because these sublingual tablets require daily dosing. RC would need to discuss with her provider her desire for daily dosing or travel to the clinic for routine injections.

RISKS

CASE 20-6, QUESTION 6: RC asks about the risks associated with either the shot or the sublingual tablet.

Local adverse reactions (i.e., redness, swelling) to SCIT can be common, but the risk of severe reaction (i.e., anaphylaxis) is low.[1] Sublingual tablets are FDA approved for administration after the first dose because of the perceived safety profile. Because of the risk of anaphylaxis, patients should have access to and be taught on the proper use of epinephrine autoinjector.[1] In view of the occasional occurrence of systemic side effects, it is important that if R.C. receives injections then it may be administered by personnel who are fully trained and experienced in the early recognition and treatment of such reactions.

CASE 20-6, QUESTION 7: Should R.C. also have a prescription for an epinephrine injector for use in case of anaphylaxis? If so, how should it be used?

Yes, if RC decides to use SLIT, she will need a prescription for and education on how to administer injectable epinephrine. She should be educated to use the injection of epinephrine if signs or symptoms (such as facial itching, tongue swelling, difficulty swallowing, or shortness of breath) occur after a dose of SLIT. The Auto injector is given intramuscularly into the thigh, through clothing if necessary. RC can repeat the injection with an additional epinephrine auto-injector as necessary.[29] See Table 20-9 for available injectable epinephrine products.

Table 20-9

Available Injectable Epinephrine Products

Product name	Dosage form and strength	Adult dose	Pediatric dose
EpiPen Jr 2-Pak	Solution Auto-injector 0.15 mg/0.3 mL	N/A	Dosage based on patient body weight: 15–29 kg: 0.15 mg IM or subcutaneously; ≥30 kg: 0.3 mg IM or subcutaneously
EpiPen 2-Pak	Solution Auto-injector 0.3 mg/0.3 mL	0.3 mg IM or subcutaneously into the anterolateral aspect of the thigh

DRUG-INDUCED NASAL CONGESTION: RHINITIS MEDICAMENTOSA

CASE 20-7

QUESTION 1: L.K. is a 27-year-old man who has suffered intermittent symptoms of allergic rhinitis for several years. He reports that his symptoms are most bothersome in the spring and associated with blooming of various grasses. During these periods, he has typically used oral chlorpheniramine (4 mg every 6 hours), which relieves his symptoms but makes him drowsy at work. This season, he reports that his symptoms have been more severe, with sneezing, runny nose, and extreme itching in his nose. He tried oral loratadine (10 mg daily) with partial relief of symptoms. He also states that nasal congestion has been more of an issue with this episode and to address this he has used xylometazoline nasal spray (0.1% solution) for the past 3 weeks. Despite increasing the use of nasal spray from two sprays per nostril twice daily to three sprays per nostril 4 times a day, he reports that the congestion is getting worse. What might be an explanation for L.K.'s increasing need for nasal decongestant?

Selected medications and some drugs of abuse can cause nasal congestion through a variety of mechanisms.[65] Table 20-10 lists agents associated with drug-induced nasal symptoms. In this case, L.K. is likely experiencing rebound nasal congestion as a result of a specific form of drug-induced rhinitis called rhinitis medicamentosa (RM).

Topical decongestants are indicated for short-term use. When used acutely, sympathomimetic (adrenergic) agents stimulate α-adrenergic receptors on blood vessels, resulting in vasoconstriction (which serves to relieve nasal congestion associated with edematous, congested blood vessels).[65] But when these agents are used chronically, this can result in overstimulation of α-adrenergic receptors leading to tachyphylaxis, and decreased production of endogenous norepinephrine through a negative feedback mechanism.[65] RM has also been associated with the presence of benzalkonium chloride as a preservative in some nasal products.[66]

When RM occurs, many patients will attempt to treat the rebound congestion by using the offending topical decongestant more frequently and/or at increased doses, creating a vicious cycle. L.K.'s description of using the xylometazoline for an extended period of time (3 weeks), more frequently (from twice daily to 4 times daily) and at high doses (from two sprays per nostril to three sprays per nostril) support the diagnosis of RM.

CASE 20-7, QUESTION 2: How should L.K.'s rhinitis medicamentosa be managed?

Table 20-10

Drugs Capable of Causing Nasal Symptoms

Local Inflammatory Mechanisms
Aspirin Nonsteroidal anti-inflammatory drugs
Neurogenic Mechanisms
Centrally Acting Sympatholytics

Strategies for Resolution

The best strategy for managing RM is prevention, by limiting the duration of topical decongestant use to no more than 3 to 5 days.[29] When these medications must be used for longer than 5 days, the patient should be advised to take a 1- to 2-day holiday during which the topical agent is not used before resuming treatment. Patients should be counseled about this whenever topical decongestants are recommended or purchased. When preventative strategies fail, several options for treatment exist.[66]

The first step is to discontinue the offending topical decongestant. L.K. should be counseled to stop the xylometazoline. Because abrupt discontinuation may cause discomfort or worsening of congestion,[66] L.K. should be educated to not restart the topical decongestant. Intranasal corticosteroids (any available product) should be recommended to patients with RM and may need 6 weeks to reach full effect.[65,66] Because L.K. is experiencing RM plus symptoms (sneezing, runny, and itchy nose) that occur seasonally, an IN corticosteroid such as mometasone nasal spray (two sprays in each nostril daily) should be recommended. Saline nose drops or spray can be added to moisturize and alleviate any nasal irritation. In refractory cases, a short course of systemic corticosteroids may be necessary.[66] Note that if the patient has used the topical decongestant continuously for many months or even years, the nasal mucosa may have undergone irreversible changes.

IDIOPATHIC RHINITIS

Diagnosis

CASE 20-8

QUESTION 1: M.S., a 29-year-old man, complains of profuse watery rhinorrhea that has been a chronic and progressively worsening problem for the past 5 years. He also experiences some nasal congestion with the rhinorrhea, but denies nasal itching or sneezing. Although the symptoms tend to remit and exacerbate, they do not occur in any definable seasonal pattern. His symptoms are worsened by exposure to tobacco smoke, strong fumes such as paint or ammonia, and cold air. These often are associated with headaches. M.S. has no other medical problems and no family history of allergies. He does not smoke and rarely drinks alcohol. His only medication, mometasone (50 mcg/spray, two sprays in each nostril once daily as needed), only partially relieves the symptoms. M.S. sniffs and blows his nose several times during the medical history taking. Physical examination reveals a mildly erythematous nasal mucosa and a minimally edematous inferior turbinate. Copious nasal discharge is clear and watery and air movement through the nose is relatively good. There is no sinus tenderness. The remainder of his physical examination is normal. Microscopic examination of a nasal smear demonstrates only a few neutrophils and no eosinophils. What information about M.S. supports the diagnosis of idiopathic rhinitis?

Idiopathic rhinitis is a diagnosis of exclusion encompassing those patients with nasal mucous membrane inflammation with no proved immunologic, microbiologic, pharmacologic, hormonal, or occupational cause.[6] The syndrome is sometimes called nonallergic rhinitis or "vasomotor rhinitis", but using this terminology can be confusing because the cause of the symptoms has still not been clearly identified.[6] The prevailing theories involve local atopy, dysfunction of both or either the autonomic nervous system or nociceptive nerve sensor and ion channel proteins.[7] Theoretically, this is the reason that stimuli that normally increase parasympathetic activity in the nose, such as cold air and inhaled irritants, aggravate symptoms.[7] Still, substantial debate exists over whether idiopathic rhinitis represents a localized allergic response in the absence of systemic atopic markers as well as the evidence for inflammatory pathophysiology in the disease.[6]

CASE 20-8, QUESTION 2: M.S. asks what causes idiopathic rhinitis and what can be done to alleviate his symptoms.

The symptoms of idiopathic rhinitis are variable. Most patients experience perennial nasal obstruction accompanied by profuse, watery nasal, and postnasal discharge. Many patients complain of nasal obstruction as the primary symptom, whereas for others it is rhinorrhea. Sneezing, nasal itching, and conjunctival symptoms are rare.[7] Headache may occur and usually is frontal or localized over the bridge of the nose. Symptoms may also appear or worsen in response to climatic changes such as temperature, barometric pressure, and humidity.[7] Similarly, irritant triggers such as tobacco smoke, industrial pollutants, strong odors and perfumes, newsprint, and chemical fumes may worsen or aggravate symptoms.[7]

The appearance of the nasal mucosa also is variable. The turbinates are usually erythematous and, during an exacerbation, considerable quantities of nasal secretions, which can lead to crusting and dryness, may be present.[6] Nasal eosinophilia is not present and skin-prick testing results are usually negative.[7]

M.S.'s symptoms of bothersome watery rhinorrhea, nasal congestion, and headache without itching or sneezing are typical. His complaint of worsening symptoms with exposure to noxious inhalants and cold air supports the diagnosis of idiopathic rhinitis. The nasal smear, which notably lacks large numbers of eosinophils, initially differentiates this disease from nonallergic rhinitis with eosinophilia syndrome. This disorder has similar symptoms but also is marked by nasal eosinophilia (5%–20%) in the setting of negative skin-prick testing and negative IgE levels.[7]

Choice of Therapeutic Agent

CASE 20-8, QUESTION 3: What nonpharmacologic and pharmacologic treatments are appropriate to manage M.S.'s idiopathic rhinitis?

Patients should be instructed to avoid as many aggravating factors as possible, such as strong odors (perfumes, soaps, paints) and air pollutants (smoke and tobacco fumes).[6] Saline irrigation is valuable as a general soothing and moisturizing treatment.[6] Pharmacotherapy for idiopathic rhinitis should be directed toward the predominant symptoms of the individual patient. For patients with predominant nasal congestion and minimal rhinorrhea, the intranasal corticosteroids may be helpful.[6,67] The addition of oral decongestants may improve nasal obstruction in some patients with idiopathic rhinitis, but should be considered adjunctive therapy because side effects can be problematic and data regarding efficacy is lacking.[6]

M.S.'s case is typical of the often frustrating course in treating idiopathic rhinitis. Commonly, multiple therapeutic plans fail, and M.S. has responded incompletely and unsatisfactorily to intranasal corticosteroids. There is some older evidence suggesting topical nasal capsaicin may be effective, but this option has not garnered widespread support.[6] Surgical treatments have been attempted for patients in whom medical management fails, although it is typically reserved for patients with concomitant nasal septal deviation or turbinate hypertrophy.[6]

In patients such as M.S., who have rhinorrhea as their predominant symptom, FGAs may be helpful because of their anticholinergic drying effects.[6] The topical antihistamine, azelastine, has been shown to be efficacious for symptoms including congestion, postnasal drip, and sleeping difficulty in those with idiopathic rhinitis.[6] Another option for decreasing nasal secretions is nasal ipratropium bromide, a topical anticholinergic agent with minimal adverse effects[6] (see Table 20-6 for dosing information). In the case of M.S., because he has been comfortable using an intranasal product (mometasone) in the past, it would be reasonable to initiate a trial of ipratropium bromide 0.03% two sprays in each nostril 3 times daily. Once the rhinorrhea is controlled, he should be advised to reduce the dosage to twice daily. Nasal saline can also be used as needed if excessive dryness occurs during dosage optimization.

MIXED ALLERGIC–NONALLERGIC RHINITIS

CASE 20-9

QUESTION 1: D.W. is a 56-year-old woman with a longstanding history of allergic rhinitis related to triggers with seasonal ragweed. Her primary symptoms are rhinorrhea and sneezing, which she has relieved by using various oral antihistamines (clemastine 1 mg daily and, more recently, cetirizine 10 mg daily) that she takes several weeks each autumn. Recently (during winter), she has experienced new rhinitis symptoms associated with the weather and various odors that were not a problem in the past, specifically, perfumes and food spices. When she encounters these, she exhibits watery rhinorrhea and profound congestion. She has tried a combination of cetirizine with pseudoephedrine for these episodes, but reports that it "doesn't seem to help much and it makes me feel jumpy." Are D.W.'s new symptoms the result of breakthrough (uncontrolled) allergic rhinitis or do they represent something new?

Distinguishing between allergic rhinitis and nonallergic rhinitis may be difficult in clinical practice, and the presence of concomitant allergic and nonallergic rhinitis in some patients confounds the diagnosis further.[8] A careful history should be gathered from the patient and an assessment made of the temporal nature of the symptoms and various exposures. The Clinical Presentation and Assessment of Rhinitis section in this chapter can be helpful to review to help distinguish between allergic and nonallergic causes of rhinitis. When a patient presents with characteristics suggestive of both types, especially in the case of new symptoms or triggers despite optimized therapy, mixed rhinitis should be considered.

Although D.W. has a confirmed history of ragweed pollen sensitivity (supporting the allergic rhinitis diagnosis), the timing of the more recent symptoms and the new triggers (i.e., odors) suggest that she may have developed sensitivities of a nonallergic (non–IgE-based) nature. The patient's age also is consistent with the development of vasomotor rhinitis (nonallergic), which can present around the time of menopause. This, combined with the lack of efficacy from a previously successful therapy (i.e., oral antihistamine), suggest that D.W. may be exhibiting a mixed allergic–nonallergic rhinitis presentation.

CASE 20-9, QUESTION 2: How should D.W.'s mixed rhinitis be treated? How is this different from the management of allergic rhinitis?

The important point about nonallergic triggers, or new onset triggers such as those present in D.W., is that oral antihistamines and other therapies directed primarily at allergic responses may be ineffective in relieving all symptoms. Good clinical evidence suggests that intranasal steroids are an effective option, as well as intranasal antihistamine therapy or a combination of the two.[8] Avoidance or minimization of exposure to the triggers is also an important strategy. For D.W., a 4-week therapeutic trial of a benzalkonium chloride-free intranasal steroid (e.g., ciclesonide two sprays in each nostril once daily) with counseling about appropriate administration is warranted. Intransal steroid therapy may improve the response to both allergic and nonallergic triggers.[8]

SUMMARY

The initial management of rhinitis should be directed at preventing symptoms, which can be achieved through a variety of pharmacologic and nonpharmacologic methods.

Treatment plans for allergic rhinitis, the most common subtype, should include patient education, allergen or irritant avoidance, and the appropriate medications, including immunotherapy, if indicated. Control of the disease process is the expected outcome, so that patients are able to live their lives comfortably without symptoms or impairment. Customizing therapy for each patient based on symptom history and response to treatments is important. Rhinitis can be controlled and effective management can greatly improve the quality of patients' lives.

Cystic Fibrosis

Paul M. Beringer and Michelle Condren

CORE PRINCIPLES

		CHAPTER CASES
1	Cystic fibrosis (CF) is a genetic disorder affecting approximately 30,000 individuals in the United States that is caused by a defect in the cystic fibrosis transmembrane conductance regulator protein, which is a chloride channel that regulates fluid and electrolyte transport within secretory epithelial cells throughout the body.	**Case 21-1 (Question 1), Figure 21-1, Figure 21-2**
2	The principal manifestations of CF include malnutrition secondary to pancreatic insufficiency and pulmonary dysfunction, resulting from chronic airway obstruction, infection, and inflammation.	**Case 21-1 (Question 1), Table 21-1, Figure 21-3**
3	Diagnosis of CF is based on newborn screening or presence of the typical signs and symptoms of the disease, and either documented abnormalities in ion transport or identification of two CF mutations.	**Case 21-1 (Questions 1, 2), Table 21-2**
4	Administration of pancreatic enzymes and fat-soluble vitamins are prescribed to correct malabsorption and vitamin deficiencies and improve nutritional status.	**Case 21-1 (Question 2), Table 21-3**
5	Key therapies for management of CF pulmonary disease include inhaled dornase alfa and hypertonic saline in combination with mechanical airway clearance techniques to combat airway obstruction, inhaled antibiotics to combat airway infection, and oral azithromycin for airway inflammation.	**Case 21-2 (Questions 1–3), Case 21-3 (Question 3)**
6	Periodically, patients will experience acute pulmonary exacerbations characterized by increased pulmonary symptoms, acute loss of lung function, and loss of weight, which require intensification of airway clearance, administration of systemic antibiotics, and nutritional supplements.	**Case 21-3 (Questions 1, 2, 4), Table 21-4**
7	Key monitoring parameters in patients with CF include trends in pulmonary function tests to determine response to therapies and identify possible acute pulmonary exacerbations, and body mass index to assess nutritional status.	**Case 21-1 (Question 3)**
8	Therapy for patients with CF should include attention to complications, including cystic fibrosis–related diabetes mellitus, osteoporosis, hepatobiliary disease, constipation, and depression. Future therapies directed against the basic defect offer a potential cure for CF.	**Case 21-3 (Question 5)**

Cystic fibrosis (CF) is a severe, complex, hereditary disease that affects 1 of every 3,200 Caucasian births, or approximately 30,000 children and adults in the United States. One in 31 Americans carries the autosomal recessive gene for CF, which arises from a mutation in coding for the cystic fibrosis transmembrane regulator protein (CFTR). This genetic mutational error results in the complex, multisystem disease of CF, which is characterized by malabsorption and a state of chronic lung obstruction, inflammation, and infection.

The course and severity of CF are variable and unpredictable. The median predicted survival age has increased from 28 to 41 years over the past two decades because of advances in the management of this disorder.[1] Although current therapy continues to rely on treatment of symptoms, several compounds in clinical development are directed at the basic defect and offer a potential cure. In the meantime, aggressive treatment with existing therapies can decrease the morbidity of this disease and increase the life expectancy of the patient.

GENETIC BASIS

CF is caused by mutations in the CFTR gene, which is a member of the ATP-binding cassette family. CFTR is dependent on cyclic adenosine monophosphate for chloride transport: defective coding for CFTR inhibits the normal regulation of ion transport in and out of the cell on the apical surface of secretory epithelial cells.[2] CFTR also regulates the transport of bicarbonate and sodium ions, mucous rheology, pulmonary inflammation, and bacterial adherence.[3–7]

Figure 21-1 Classification of mutations. Cystic fibrosis transmembrane conductance regulator (CFTR) gene mutations are categorized into six classes. Mutation classes I, II, V, and VI result in an absence or reduced quantity of CFTR protein at the cell membrane, whereas mutation classes III and IV influence the function or activity of CFTR at the cell membrane. Class I mutations are associated with the greatest disruption to CFTR-mediated chloride transport; in general, chloride transport gradually increases through the remaining five classes, with the greatest activity being observed in class IV to VI mutations. (Reprinted with permission from Derichs, N. Targeting a genetic defect: cystic fibrosis transmembrane conductance regulator modulators in cystic fibrosis. Eur Respir Rev. 2013; 22: 58-65.)

CF is an autosomal recessive disorder, which means there is a 25% chance of inheriting the malfunctioning genes from both parents and developing the disease, a 50% chance of inheriting one abnormal gene (i.e., carrier), and a 25% chance of inheriting two normal genes. Approximately 5% of whites are asymptomatic carriers of the CF mutation. More than two decades have passed since the identification and cloning of the gene responsible for CF, and nearly 2,000 CFTR mutations have been discovered (http://www.genet.sickkids.on.ca/cftr/app). These mutations have been grouped into six major classes according to the functional consequence of the defect (Fig. 21-1).[8–10] The most common variant is ΔF508, representing 66% of all mutations. Approximately 90% of all patients with CF have at least one copy of this mutation.

The importance of identifying the gene mutation relates to potential new therapies, currently, in various stages of clinical development. The greatest excitement and anticipation involves new therapies directed at the basic defect that offer a potential cure for CF. Replacement of the defective gene and repair of the dysfunctional CFTR protein are the two approaches actively being pursued.

Cystic Fibrosis Transmembrane Conductance Regulator Modulation

These therapies are designed to correct the function of the defective CFTR protein made by the CFTR gene, allowing normal chloride and sodium transport across epithelial cells lining the lungs and other organs. Several compounds are currently in clinical drug development for patients with different CFTR mutations, demonstrating a pharmacogenomic approach to CF treatment that is likely to be realized in the near future.

IVACAFTOR AND LUMACAFTOR

Ivacaftor, known as a CFTR potentiator, aims to increase the function of defective CFTR proteins by increasing the gating activity, or ability to transport ions across the cell membrane, of CFTR at the cell surface. In people with gating mutations (e.g., G551D mutation), CFTR proteins do not function normally at the cell surface (Fig. 21-1). A phase 3 trial of ivacaftor in CF patients with at least one copy of a G551D mutation demonstrated improvements in pulmonary function (absolute change of 10% in forced expiratory volume in 1 second [FEV_1]), and a 55% reduction is risk for acute pulmonary exacerbations over the 48-week study period.[11] Based on the positive

---

results of this trial in patients with the G551D mutation as well as additional trials with patients with other gating/conductance abnormalities, ivacaftor received FDA approval. Ivacaftor is currently indicated in patients aged 2 years or above, who have one of 23 residual function mutations which represent approximately 5% of the total population of CF patients worldwide. Ivacaftor alone is not effective in patients who are homozygous (have two copies) for the F508del mutation in the CFTR gene. Ivacaftor is provided in 150 mg tablets to be administered orally with a high-fat meal twice daily for patients 6 years of age and older and as 50 and 75 mg granules to be administered orally in children between the ages of 2 and 5. Ivacaftor is a substrate for CYP3A, and, therefore, co-administration with moderate or strong inducers is not recommended. In addition, dosage adjustment is necessary when co-administered with moderate or strong inhibitors of CYP3A or when used in patients with moderate or severe hepatic disease. Monitoring of liver function tests and ophthalmological exams for potential lens opacities are recommended.

Lumacaftor, known as a CFTR corrector, aims to increase CFTR function by increasing the trafficking, or movement, of CFTR to the cell surface. In people with the ΔF508 mutation, there is improper folding of the CFTR protein, leading to proteosomal degradation and failure of the CFTR protein to reach the cell surface in normal amounts (Fig. 21-1). In addition, the small amount of protein that does make it to the cell surface fails to activate properly. A phase 3 study, evaluating the combination of ivacaftor/lumacaftor in patients homozygous for the ΔF508 mutation, demonstrated a modest improvement in pulmonary function (absolute improvement in FEV_1 of 2.6%–4%) and a reduction in the rate of pulmonary exacerbations (30%–39%).[12] The recent FDA approval of ivacaftor/lumacaftor is significant since nearly 50% of the CF population are homozygous for the ΔF508 mutation.

ATALUREN

Ataluren is a novel, small-molecule compound that promotes the read through of premature truncation codons in the CFTR mRNA. It aims to treat CF patients with nonsense mutations (nmCF). A nonsense mutation is an alteration in the genetic code that prematurely halts the synthesis of an essential protein (Fig. 21-1). About 10% of people with CF have nonsense mutations. Data from a phase 3 clinical trial of ataluren in pediatric and adult patients with nmCF did not demonstrate significant differences in pulmonary function or exacerbation frequency between ataluren and placebo over the 48-week study period.[13] Additional clinical studies in patients not receiving concurrent inhaled tobramycin are currently ongoing.

Gene Therapy

Since the discovery of the CFTR gene in 1989, there has been hope that a gene therapy treatment would soon be available as a potential cure to CF. Initial attempts at gene therapy using viral vectors were hampered by low transfer efficiency and short retention within the airways as a result of host immunogenicity. An alternative approach uses plasmid DNA encapsulated within cationic liposomes to deliver the gene to the airways. Potential advantages of nonviral approaches are that they are noninfectious and relatively nonimmunogenic, can accommodate a large DNA plasmid, and may be produced simply on a large scale. A multiple-dose phase 2b clinical trial of PGM169/GL67A conducted by the UK Gene Therapy Consortium demonstrated stabilization of FEV_1 in treated versus control patients (treatment effect 3.7%) over the 1-year study period.[14]

Interestingly, even among individuals with identical genotypes, a broad spectrum of disease severity is seen.[15,16] The contribution of genetic factors other than the misfunctioning CFTR can have a great influence on disease severity.[17] Screening for genetic modifiers is currently a research tool that will hopefully lead to the development of new potential therapies.[18]

Table 21-1

Clinical Manifestations of Cystic Fibrosis

Manifestation	Approximate Incidence (%)	
	Children (Infants)	Adults
Pancreatic		
Insufficiency	85 (80–85)	90
Pancreatitis	1–2	2–4
Abnormal glucose tolerance	38	75

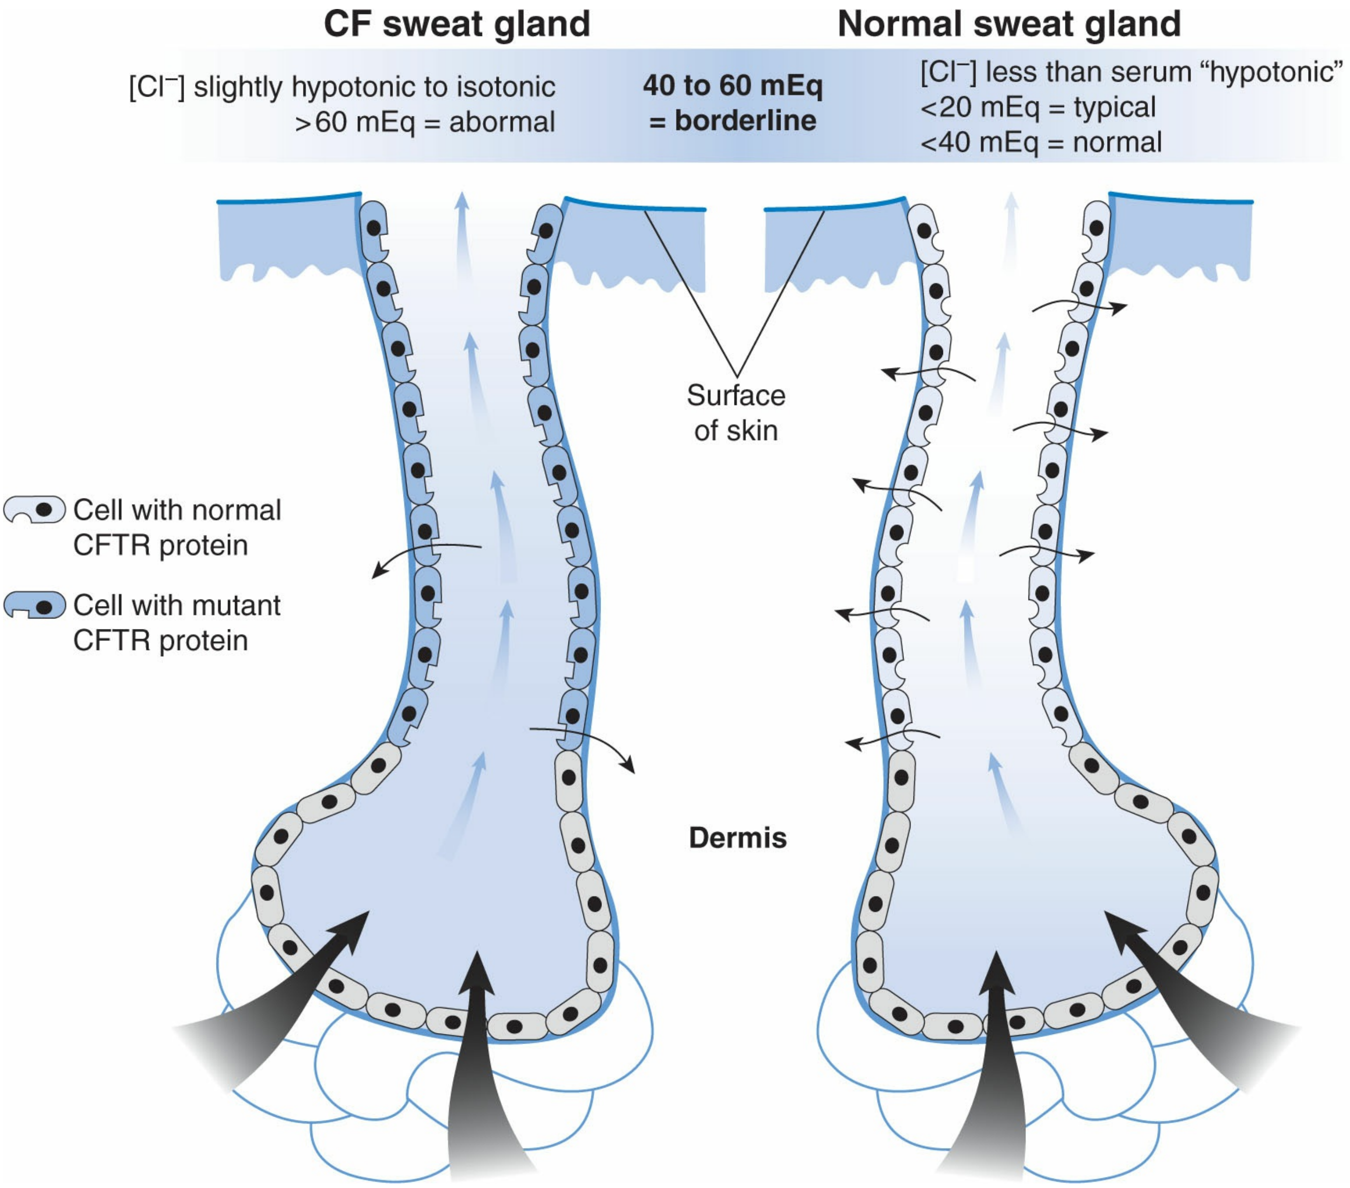
Delayed puberty		85
Infertility		
Males		98
Females		70–80

CLINICAL MANIFESTATIONS

Genotype, environmental factors, and modifier gene status all contribute to the highly variable clinical course of CF. The linking of the loss of CFTR function to clinical manifestations of the disease, however, has been central to gaining an understanding of the disease and in the discovery of new therapies. Normally, CFTR is highly expressed on the membranes of epithelial cells of the lungs, sweat glands, salivary glands, male genital ducts, pancreas, kidney tubules, and digestive tract. The CFTR performs different functions in specific tissues; therefore, a dysfunctional or absent CFTR has different effects on different organs, resulting in the multiorgan clinical manifestations of CF (Table 21-1).

Sweat Glands

Fluid secreted by the sweat glands in patients with CF is normal, but a defect in the reabsorption of electrolytes leads to sweat with a high salt content. CFTR, in the apical membrane of the resorptive area of the sweat gland, functions as an ion channel for chloride transport and also activates an associated epithelial sodium channel.[19] Normally, these channels efficiently reabsorb sodium chloride from sweat. In patients with CF, loss of these functioning channels blocks the ability of the sweat ducts to reabsorb salt, leading to elevated sweat sodium chloride concentrations (Fig. 21-2). The loss of these sodium and chloride ion channels serves as the basis for the diagnostic sweat chloride test.



CF sweat gland
Normal sweat gland
[Cl⁻] slightly hypotonic to isotonic
>60 mEq = abormal

Figure 21-2 Chloride transport in sweat glands of normal and cystic fibrosis individuals. (Source: Lyczak JB, et al. Lung infections associated with cystic fibrosis. Clin Microbiol Rev. 2002;15(2):194–222.)

Pancreatic Involvement

The exocrine and ultimately the endocrine functions of the pancreas are affected in CF. Pancreatic enzymes normally are secreted into bicarbonate-rich fluid from the pancreatic duct. The loss of CFTR function inhibits secretion of digestive enzymes and bicarbonate into the duodenum, resulting in ductal obstruction. With time, these enzymes (lipase, protease, and amylase) accumulate and eventually begin to digest the pancreatic tissue.[5,20] The term cystic fibrosis arises from the fibrotic scar tissue that replaces the destroyed pancreas. Without these enzymes, there is poor digestion of fats and, to a lesser extent, proteins and carbohydrates. As a result, 90% of patients with CF experience pancreatic insufficiency characterized by steatorrhea (fatty stools), decreased absorption of the fat-soluble vitamins (A, D, E, and K), malnutrition, and failure to thrive. Early in life, serum concentrations of amylase and lipase are increased secondary to pancreatic autodigestion. This destructive process can result in either painful or asymptomatic chronic pancreatitis.

Eventually, the progressive destruction of the pancreas affects its endocrine function, leading to cystic fibrosis–related diabetes mellitus in 15% to 20% of adolescents and nearly 40% of adults between the ages of 20 and 30.[21] The additional diagnosis of diabetes in CF is associated with more rapid decline in lung function and shortened survival. Early aggressive insulin therapy can result in improved clinical outcomes.

Gastrointestinal Involvement

Meconium ileus, an intestinal obstruction at birth, occurring in 20% of newborns with CF, is an inheritable trait of this disease.[22] Outside the neonatal period, distal intestinal obstruction syndrome (DIOS, also called meconium ileus equivalent) can occur at any age and results from the complete or partial obstruction of the intestine. Intestinal obstruction occurs in 10% to 20% of patients and results from the inspissation of intestinal secretions and incompletely digested intestinal contents. A right lower quadrant mass, abdominal distension, failure to pass stools, and vomiting can accompany DIOS.

Gastroesophageal reflux disease (GERD) is common in both children and adults with CF.[23–25] Children with CF should be screened for GERD and treated, if diagnosed. Other intestinal complications include rectal prolapse, intussusception, and appendiceal abscesses.

Hepatic Involvement

Located on the apical surfaces of the cells lining the intrahepatic and extrahepatic bile ducts and the gallbladder, CFTR functions to facilitate ion transport.[26] In patients with CF, the abnormal chloride efflux across the cells results in the reduction in water and sodium movement into the bile. The

---

resulting decrease in the volume and flow of bile leads to stasis and obstruction of the biliary tree. With chronic obstruction, there is inflammation, giving rise to the characteristic lesion of focal biliary cirrhosis.[27]

Liver disease develops in the first decade of life. Significant liver disease is seen in 13% to 25% of children with CF.[28–30] Prevalence rates may be underestimated. Progressive cirrhosis is associated with portal hypertension, hypersplenism, esophageal varices, ascites, and, in a small number of patients, complete hepatic failure requiring transplantation. Approximately 30% of adult patients with CF have abnormal gallbladder function and size (absent or small gallbladder) with 5% to 10% of patients forming gallstones.[31]

Genitourinary Involvement

Approximately 98% of male patients with CF are infertile secondary to in utero obstruction of the vas deferens or related structures. Hormonal secretion and secondary sexual characteristics are normal. In a small number of patients, infertility can be the only manifestation of disease, and CF may go undiagnosed until fertility testing is performed. The prevalence of infertility is higher in women with CF and hypothesized to be related to the production of thick and tenacious cervical mucus. Hundreds of pregnancies have been carried successfully to term, but these are not without risk, especially for patients with moderate to severe pulmonary disease.[32]

Bone and Joint Involvement

Patients with CF have low bone mineral density, slower rate of bone formation, accelerated rate of bone loss, and arthritis.[33,34] Osteoclastic precursors are elevated during acute pulmonary exacerbation.[35] Although early, aggressive treatment of pulmonary exacerbations can improve bone health, sufficient intake and absorption of the fat-soluble vitamins, D and K, are important, and oral bisphosphonates may also be indicated.[36]

Patients with CF often suffer from intermittent arthritis symptoms, but only about 2% of patients have persistent symptoms. The three types of intermittent CF arthritis are (a) hypertrophic osteoarthropathy, (b) immunoreactive, and (c) CF arthropathy. The first two types are associated with pulmonary disease flare-up. The third type, CF arthropathy, affects large joints and may be accompanied by fever and erythema nodosum.[37–40]

Sinus Involvement

Nasal polyps, which are outgrowths of normal sinus epidermis, can be found in up to 20% of older patients with CF and may become sufficiently large to block nasal passages. The pathogenesis of these polyps is unknown, but the obstruction of nasal passages can lead to infection. The faulty ionic transport of chloride across the apical membrane of epithelial cells lining exocrine glands leads to dehydration of extracellular fluids and the development of inspissated mucus in nasal and sinus passages. Nearly all patients with CF (90%–100% of patients >8 months of age) develop sinus disease. On radiographic examination, greater than 90% of adult-age patients have pansinusitis, which can contribute to pulmonary exacerbations.[41,42] The impact of sinusitis on the CF population is significant.

Pulmonary Involvement

Respiratory disease is of major importance in patients with CF because it is the principal cause of repeated hospitalizations, decline in pulmonary function, and death. Although the exact pathophysiological mechanisms leading from the CFTR cellular defect to the development of bronchiectasis and loss of pulmonary function are not currently known, research in the past two decades since the discovery of the genetic defect has greatly expanded our understanding of this process.

Figure 21-3 Pathophysiology of cystic fibrosis lung disease. Treatments in italics are investigational. **A:** Normal airway epithelia with functional CFTR demonstrates normal mucociliary clearance. **B:** CFTR defect leads to reduced periciliary liquid and loss of mucociliary clearance. Accelerated ion transport (sodium reabsorption) leads to increased oxygen consumption (QO_2) and hypoxic gradients (pO_2) in the airways. **C:** Impaired mucociliary clearance leads to accumulation of mucous within the airways causing airway obstruction. **D:** Retained secretions provide an optimal environment for initial infection. **E:** Chronic P. aeruginosa infections form microcolonies (i.e., biofilms) which resist host defenses as well as antibiotics. **F:** A chronic inflammatory response mediated by neutrophil recruitment to the airways leads to release of reactive oxygen species and proteases which damage the airways. (Reprinted with permission from Worlitzsch D et al. Effects of reduced mucus oxygen concentration in airway Pseudomonas infections of cystic fibrosis patients. J Clin Invest. 2002;109:317.)

AIRWAY OBSTRUCTION, INFECTION, AND INFLAMMATION

One of the leading theories regarding the pathogenesis of airway disease in CF is depicted in Figure 21-3.[43] The lower airways of a

---

normal lung are maintained free of pathogens through various lung defense mechanisms. For example, a thin film of liquid on the airway surfaces called the airway surface layer (ASL) contains antimicrobials, antioxidants, proteases, and other substances that work to eliminate pathogens. In addition, the ASL can remove invading microbes from the lung by moving a mucous gel toward the mouth through ciliary motion. Mucociliary clearance of microbes and debris is aided by the cough reflex to keep the airways clear. Because coughing is an important defense mechanism, cough suppressants should not be used in patients with CF.

In patients with CF, the CFTR defect reduces the ASL, resulting in markedly thickened mucus and impaired mucociliary clearance. Continued mucus hypersecretion leads to mucus plugging and airway obstruction. Additionally, the CFTR defect causes acidification of the ASL secondary to reduced bicarbonate secretion, resulting in increased susceptibility to infection.[44] Accelerated ion transport increases oxygen consumption, leading to hypoxic gradients within the mucus. Pseudomonas aeruginosa adapts to the anaerobic environment by increasing alginate production and through the formation of biofilms. In response to infection, proinflammatory cytokines (e.g., tumor necrosis factor-α, interleukin [IL] 1), chemokines (e.g., IL-8), and other inflammatory mediators (e.g., leukotriene B_4) are released from airway epithelial cells and alveolar macrophages, resulting in neutrophil recruitment into the airways. Because the neutrophils undergo apoptosis, they release their DNA, which accumulates and contributes to airway obstruction. In the normal host, proteases (e.g., neutrophil elastase) are released in response to an infectious insult and digest the bacteria, while lung tissue is protected by the presence of antiproteases. In patients with CF the intense neutrophilic infiltration in response to IL-8 results in an imbalance between airway proteases and antiproteases.[45] The excess proteases cause degradation of elastin, a structural component of the airways. In addition, airway proteases degrade cell surface receptors (e.g., CXCR1 from neutrophils), leading to impaired bactericidal activity accounting for the persistence of P. aeruginosa within the airways despite a robust inflammatory response.[46] The chronic cycle of airway obstruction, infection, and inflammation leads to bronchiectasis, progressive loss of lung function with eventual respiratory failure, and death.

MICROBIOLOGY

The microbiology of airways in patients with CF changes as a function of age. In infants and toddlers, the principal organisms include nontypeable Haemophilus influenzae and Staphylococcus aureus. The prevalence of methicillin resistant S. aureus has increased dramatically in the last 5 years and has been associated with a more rapid decline in pulmonary function and increased mortality.[47,48] Clinical trials evaluating antibiotic therapy for eradication of MRSA as well as chronic suppressive therapy are currently ongoing. In older children and adults, P. aeruginosa becomes the predominant pathogen. Other unique pathogens in CF include Burkholderia cepacia and Aspergillus fumigatus.

Pseudomonas Aeruginosa

Infections with P. aeruginosa occur in three distinct phases. First, the patient acquires the organism and presents with an initial infection. Treatment often leads to eradication; however, reinfection eventually occurs and leads to chronic infection. Under pressure from hypoxic gradients within the mucus, P. aeruginosa within the airways converts to the mucoid phenotype. Observational studies have noted significant structural as well as functional changes within the lung in patients with sputum cultures that grow mucoid P. aeruginosa when compared with patients with nonmucoid strains or who are not infected with P. aeruginosa. Specifically, when compared with patients with nonmucoid P. aeruginosa, those with mucoid P. aeruginosa had significant abrupt declines in percentage of predicted FEV_1.[49] The median time to acquisition of nonmucoid and mucoid strains is 1 and 13 years, respectively; however, there is tremendous variability in the initial acquisition and development of chronic infection. Some patients avoid acquisition of P. aeruginosa until their adolescent years, whereas others acquire mucoid P. aeruginosa early in childhood (e.g., 5–6 years of age). Patients with delayed acquisition of P. aeruginosa typically have minimal lung disease and few hospital admissions when compared with children who acquire P. aeruginosa (in particular mucoid P. aeruginosa) earlier in life. The relatively long period between nonmucoid and mucoid P. aeruginosa offers an opportunity for intervention with pharmacologic therapy designed to eradicate the organism from the airways. The mucoid strains create a significant therapeutic challenge because they can develop into biofilms. A biofilm is a community of bacteria that adheres to tissues (e.g., airway epithelial cells) and secretes a slimy coating (mucoid exopolysaccharide), which protects it from the hostile environment within which it resides. P. aeruginosa biofilms create a therapeutic challenge when compared with their planktonic (freely motile) bacterial counterparts, because they evade local defense mechanisms, are slow growing, and can sequester β-lactamase.

Burkholderia Cepacia

Occasionally infections involve atypical organisms, including B. cepacia (2.8%). B. cepacia is actually a complex consisting of several distinct species. Burkholderia cenocepacia is the most frequently isolated and clinically relevant species in patients with CF. B. cepacia is easily transmitted via inhalation or contact with a reservoir of B. cepacia, including other patients with CF, health care professionals, or contaminated medical instruments. Colonization with B. cepacia can manifest as chronic asymptomatic carriage, progressive deterioration of lung function, or fatal decline during a short interval often associated with septicemia (known as B. cepacia syndrome), and is associated with a 50% reduction in life expectancy.[50] B. cepacia is intrinsically resistant to many antibiotics, including aminoglycosides and β-lactams, which limits treatment options. Because of the adverse health outcomes and limited treatment options, chronic infection with B. cenocepacia is a relative contraindication to lung transplantation at many centers, emphasizing the importance of preventing acquisition of this organism through active infection control measures.

Aspergillus Fumigatus

Aspergillus species present a unique challenge in patients with CF. The presence of this organism often ignites an immunologic response characterized by an increase in serum immunoglobulin E and eosinophilic infiltration of the alveoli. This syndrome is referred to as allergic bronchopulmonary aspergillosis. The typical symptoms of this syndrome include wheezing, shortness of breath, low-grade fever, and production of thick, brownish, or bloody sputum. This disease is not invasive; however, chronic eosinophilic infiltration can lead to bronchiectasis and lung scarring. Allergic bronchopulmonary aspergillosis is present in approximately 10% of patients with CF and accounts for 10% of acute pulmonary exacerbations. The diagnosis of allergic bronchopulmonary aspergillosis can be challenging owing to the overlap in clinical features with acute pulmonary exacerbations. A consensus conference sponsored by the Cystic Fibrosis Foundation provides guidelines for diagnosis and treatment of allergic bronchopulmonary aspergillosis in patients with CF.[51] The minimal diagnostic criteria include clinical deterioration, elevated total serum immunoglobulin E (greater than 500 international units/mL), positive immediate A. fumigatus skin test or serum immunoglobulin E antibodies, and A. fumigatus serum precipitins or immunoglobulin G antibodies or radiographic changes. Annual screening of serum immunoglobulin E concentrations is recommended for patients with CF older than 6 years of age.

Table 21-2

Phenotypic Features Consistent with Diagnosis of Cystic Fibrosis

Persistent colonization or infection with typical CF pathogens (e.g., S. aureus, nontypeable H. influenzae, P. aeruginosa, and B. cepacia
Chronic cough and sputum production
Persistent chest radiograph abnormalities
Airway obstruction manifested by wheezing and air trapping
Nasal polyps; radiographic or computed tomographic abnormalities of paranasal sinuses
Digital clubbing
Meconium ileus, distal intestinal obstruction syndrome, rectal prolapse
Pancreatic insufficiency, recurrent pancreatitis
Chronic hepatic disease
Failure to thrive, hypoproteinemia, and edema, complications secondary to fat-soluble vitamin deficiency
Salt loss syndromes: acute salt depletion, chronic metabolic alkalosis
Male urogenital abnormalities resulting in obstructive azoospermia (CBAVD)

CBAVD, congenital bilateral absence of the vas deferens.

DIAGNOSIS

The diagnosis of CF can be made soon after birth through newborn screening or later in life based on the presentation of symptoms. A newborn screening test based on measurement of trypsinogen concentrations in blood is performed for early diagnosis of CF. Trypsinogen is normally produced in the pancreas and is carried to the small intestine, where it changes from an inactive proenzyme to the active enzyme trypsin, which is used in digestion of proteins. In infants with CF, mucus can block the ducts from the pancreas into the small intestine. The mucus prevents trypsinogen from reaching the intestines, resulting in accumulation in the blood. This process can be detected and measured because immunoreactive trypsin (IRT) levels increase in the blood of the infant. The IRT testing is a screening test; confirmatory testing including a sweat chloride test and DNA analysis for CF mutations should be performed in infants with a positive IRT.[52]

When the pilocarpine iontophoresis test (i.e., sweat chloride test) is conducted at a certified CF center and is positive (≥60 mM), the diagnosis of CF can be applied. In infants younger than 6 months of age, a sweat chloride value of 30 to 59 mM indicates possible CF and should be repeated in conjunction with DNA analysis.[52] In infants older than 6 months of age, a value of 40 to 59 mM indicates possible CF and should be repeated in conjunction with DNA analysis.

DNA analysis is recommended and is expected to identify 90% of CFTR mutations. The DNA analysis used for population screening is not as sensitive at detecting CFTR mutations in non-white populations. Prenatal screening for the presence of a CF carrier state in the parents is recommended by the American College of Medical Genetics and the American College of Obstetrics and Gynecology.[53]

Symptoms Suggestive of Cystic Fibrosis

For those in whom CF may not have been detected by newborn screening, the suspicion for CF is raised by clinical symptoms. Infants born with meconium ileus, an intestinal obstruction attributable to thickened meconium, at birth are highly likely to have CF. Other clinical symptoms that require further diagnostic testing are listed in Table 21-2. Presence of these symptoms warrants obtaining a sweat chloride and DNA analysis.

CASE 21-1

QUESTION 1: K.M. is a 1-week-old girl weighing 2.9 kg, who presents for routine follow-up. Her birth weight was 2.7 kg. She is growing well on breast milk every 3 hours. A review of systems reveals no abnormalities. K.M.'s newborn screening panel has returned with an elevated IRT concentration.

What further testing is recommended to determine whether this infant has CF?

At this time, it is recommended that K.M. have a sweat chloride test and DNA analysis performed. If K.M. has a positive sweat chloride, additional testing is recommended to determine whether she has pancreatic insufficiency. The preferred testing method is the fecal elastase, which is measured in a single stool sample. Fecal elastase is not degraded during intestinal transit and has been shown to correlate well with duodenal lipase, amylase, trypsin, and bicarbonate concentrations. A low value indicates the presence of pancreatic insufficiency necessitating enzyme supplementation. Although 25% of infants with CF are pancreatic sufficient at the time of diagnosis, most will become pancreatic insufficient in the first year of life.[52] For those at least 8 years of age, a serum trypsinogen may be used to assess pancreatic function.

EARLY INTERVENTIONS AND THERAPY

CASE 21-1, QUESTION 2: K.M. returns to the clinic 2 weeks later. Testing has revealed a sweat chloride of 84 mM and the presence of homozygous ΔF508 mutations. Fecal elastase is low, and the diagnosis of pancreatic insufficiency is made. What therapy should be initiated at this time?

K.M. now meets the diagnostic criteria for CF with pancreatic insufficiency. Early nutritional therapy to ensure appropriate growth is essential as good nutritional status has been associated with improved pulmonary outcomes.[54] CF patients are hypermetabolic and do not absorb fats and proteins normally. Therefore, the CF diet must be high in calories, fat, and protein. It is recommended that those with CF have an energy intake of 110% to 200% of that recommended for the general population.[55] If K.M. has difficulty gaining weight, the frequency of breast-feeding may need to increase or she will need to be changed to a high-calorie infant formula.

Vitamin and Mineral Supplementation

The malabsorption of fats in patients with CF with pancreatic insufficiency also results in decreased gastrointestinal absorption of the fat-soluble vitamins (A, D, E, and K). Approximately 45% of the CF population is deficient in one of these vitamins, even when pancreatic enzymes are being used appropriately.[56] The current recommendations for replacement therapy are listed in Table 21-3.[57] Concerns about inadequate supplementation of vitamins D and K resulting in poor bone health have arisen.[58,59] Calcium supplementation will be needed for those receiving inadequate calcium in their diet. Iron supplements might also be needed if iron deficiency anemia occurs.

Table 21-3

Daily Recommended Doses of Fat-Soluble Vitamins for Patients with Cystic Fibrosis and Vitamin Content in Specialty Vitamin Formulations

Age	Vitamin A (International Units)	Vitamin E (International Units)	Vitamin D (International Units)	Vitamin K (mg)
0–12 months	1,500	40–50	400	0.3–0.5
1–3 years	5,000	80–150	400–800	0.3–0.5
4–8 years	5,000–10,000	100–200	400–800	0.3–0.5
>8 years	10,000	200–400	400–800	0.3–0.5

Libertas	16,000 (88% β carotene)	200	1,000	0.8

K.M. should be started on a CF-specific liquid multivitamin preparation at a dose of 1 mL once daily. Additional vitamins may be supplemented if laboratory monitoring reveals an abnormality. Additionally, K.M. should receive 1/8 teaspoon of table salt per day to account for sodium loss in sweat.[60] At 6 months of age, the dose increases to 1/4 teaspoon. For bottle-fed infants, a small amount of salt is added to each feeding. For K.M., who is breast-fed, the parents should attempt pumping and bottle-feeding with breast milk twice a day to add salt. If K.M. does not tolerate bottle-feeding, the salt is not supplemented, and they should ensure K.M. is not exposed to warm conditions for a prolonged time.

Enzyme Supplementation

The mainstay of treatment for pancreatic insufficiency is exogenous replacement of pancreatic digestive enzymes. The goals of pancreatic enzyme supplementation are to (a) improve weight gain, (b) minimize steatorrhea, and (c) eliminate abdominal cramping and bloating. Supplementation with currently available therapies does not fully restore fat absorption, and the absorption of sufficient fat-soluble vitamins continues to be problematic.[61] The digestive enzymes (lipase, protease, and amylase) are available in a mixture of approximately one part lipase to three parts protease and three parts amylase in capsules that contain enteric-coated microspheres of these enzymes. The enteric coating protects these enzymes from gastric acid. Because the breakdown of fat is the most important function of these enzymes, dosing is based on the lipase content, and the dose varies according to weight, age, dietary fat intake, and symptom severity. The initial dose for infants is 2,000 to 5,000 units of lipase per breast-feeding or per 120 mL of bottle-feeding. Infants eating solid food begin at a dose of 1,000 units/kg/meal.[60] For children older than 4 years of age, 500 units of lipase/kg/meal is the initial dose for enzyme supplementation.[55] A full dose is taken with meals, and half the prescribed dose is taken with snacks. Subsequent dosing adjustments are titrated to response. Lack of weight gain, smelly, greasy stools, and abdominal pain or bloating might be indicative of insufficient enzyme supplementation.[62,63]

High-strength pancreatic enzymes have been associated with colonic strictures, which are accompanied by symptoms similar to that of DIOS. Although cause and effect have not been firmly established, doses greater than 6,500 units of lipase/kg/meal

---

have been associated with stricture formation. As a result, most recommend that the daily dose of lipase not exceed 10,000 units of lipase/kg or 2,500 units of lipase/kg/meal.[55]

When patients require unusually high doses of enzyme supplements, it sometimes can be attributable to high gastric acidity. The enteric coating on the pancreatic enzyme microspheres dissolves at a pH of 5.8, and the enzymes are destroyed at a pH of 4.0. Patients with CF have longer postprandial periods when the pH is less than 4.0 in the bowel and also have significantly less time when the pH is greater than 5.8. Because enzymes may be less effective when the bowel pH is very low,[64,65] adding a histamine type H_2 antagonist or a proton-pump inhibitor to increase gastric pH might help lower the enzyme dosing requirement.[66–68]

K.M. should receive a pancreatic enzyme supplement of 2,000 to 5,000 units per feeding. Even though K.M. is not yet eating solid food, the capsule may be opened and the contents sprinkled on a small amount (e.g., a baby's spoonful) of rice cereal, baby food, or applesauce and given before each feeding. K.M.'s caregivers should ensure that no beads are left in her mouth after the feeding is complete.

Pulmonary Interventions

Although data on the benefits of airway clearance and bronchodilator therapy in infants are sparse, these interventions are recommended by the Cystic Fibrosis Foundation.[60] Generally, albuterol may be administered before percussion and postural drainage (see Treatment of Cystic Fibrosis Airway Disease: Mechanical Methods section) once daily in infants with CF. The frequency of treatments may be increased if symptoms become evident. Respiratory syncytial virus affects most infants and may more adversely affect those with CF. Therefore, palivizumab is recommended in those with CF who are younger than 2 years of age.[60] K.M. should receive albuterol by nebulizer or metered-dose inhaler and spacer once daily before airway clearance. She should also receive palivizumab 15 mg/kg intramuscularly once a month during respiratory syncytial virus season.

CASE 21-1, QUESTION 3: What monitoring is recommended for K.M.?

K.M.'s head circumference, height, and weight should be plotted on standard growth charts every month for the first year. The goal is for her to have a weight-for-length status of the 50th percentile.[55] After the first year, quarterly growth evaluations are recommended. From 2 to 20 years of age, the goal for growth is to achieve at least the 50th percentile for body mass index. An experienced, knowledgeable registered dietitian should meet with the family to help them understand the importance of appropriate nutrition and help develop a plan for K.M. Fasting blood glucose, liver function tests, albumin, serum electrolytes, complete blood count, prothrombin time, and vitamins A, D, and E levels should be determined now, at 1 year of age, and at least annually. An abdominal examination should be done to determine liver and spleen size and consistency at each office visit.

Pulmonary status is monitored based on clinical symptoms, auscultation of the chest, and chest radiographs until about 5 years of age, when pulmonary function testing may be performed. Oropharyngeal cultures are recommended at least quarterly to detect the presence of pathogenic bacteria.

Those with CF are at risk for CF-related diabetes, warranting annual oral glucose tolerance testing starting at 10 years of age.[21] They are also at increased risk for osteoporosis and should be assessed annually for risk factors. Bone densitometry is recommended for all adults and starting at 8 years of age in those with risk factors including low vitamin D, FEV_1 less than 50%, oral corticosteroid use greater than 90 days in a year, diabetes, delayed puberty, and body mass index less than the 25th percentile.[69] K.M. currently does not have any known risk factors for osteoporosis and is too young for bone densitometry. Her risk should be re-evaluated annually starting at 8 years of age.

Treatment of Cystic Fibrosis Airway Disease

Treatment of CF airway disease involves the use of medications and techniques to mobilize pulmonary secretions, antibiotics to manage infection, and anti-inflammatory agents to reduce airway inflammation. A summary of the current evidence for specific therapies is described in the recently published pulmonary medication guidelines.[70]

MUCOCILIARY CLEARANCE

Sputum in patients with CF is difficult to mobilize because pulmonary secretions are thick as a result of the CFTR defect, the large amounts of viscous DNA from the breakdown of white blood cells, and the bacterial debris left over from chronic infections. Mechanical clearance methods, inhaled mucolytics, and airway hydration therapies can be helpful in mobilizing pulmonary secretions.

Mechanical Methods

Methods used to mechanically break up and mobilize mucus in the pulmonary tree include traditional hand percussion and postural drainage (P&PD), oscillating positive-end pressure (OPEP) with the flutter valve, high-frequency chest-wall oscillation (HFCWO), intrapulmonary percussive ventilation, and autogenic drainage (a technique of deep-breathing exercises).

For a video of how one of the HFCWO options, the Vest, works, see the last chapter at http://www.thevest.com/resources/videos.asp.

These mechanical approaches for mobilizing mucus are about equal in efficacy, and the selection of the most appropriate one for a patient depends on the ability, motivation, preference, and resources of the patient.[71] When the traditional P&PD was compared with HFCWO and OPEP, clinical efficacy and safety were comparable, but 50% of patients preferred the HFCWO, 37% preferred OPEP, and 13% preferred P&PD.[72]

Dornase Alfa

Dornase alfa is an inhaled recombinant form of human deoxyribonuclease I, which breaks up the extracellular DNA formed by apoptotic neutrophils that contributes to airway obstruction in patients with CF. The pivotal clinical trial demonstrated improvement in pulmonary function (FEV_1 5.8% vs. placebo, $p < 0.01$) and a reduction in exacerbation frequency (28% vs. placebo, $p = 0.04$) in patients receiving dornase alfa.[73] Based on these benefits, the use of dornase alfa is recommended in all patients 6 years of age and older.[70] Consideration can be given to treating infants and toddlers as well if their clinical symptoms support the presence of airway disease. Dornase alfa is expensive, with costs averaging about $3,000/month, and the cost–benefit ratio for its use continues to be debated.[74,75] A reasonable approach is to provide a brief trial of dornase alfa (1–2 months) to determine whether there is improvement in pulmonary function and the medication is well tolerated. A longer trial (up to 1 year) may be necessary to assess its effect on hospitalization rate.

Dornase alfa is available in 2.5 mg vials and is administered once daily via a vented jet nebulizer. The drug must be stored in the refrigerator and protected from light. Patients should be instructed in the proper use and maintenance of the nebulizer and compressor system. In addition, patients should be instructed not to dilute or mix dornase alfa with other drugs in the nebulizer.

Airway Hydration Therapies

Hypertonic Saline

Inhalation of hypertonic saline (IHS) improves mucociliary clearance.[76] Hypertonic saline rehydrates the airways through osmotic flow of water. When twice-daily inhaled normal saline was compared with 7% (hypertonic) sodium chloride, no difference was noted in the primary outcome, which was the linear rate of pulmonary function decline during the 48-week study period.[77] However, patients randomly assigned to receive IHS experienced a significant reduction in exacerbations (56% decrease vs. placebo, $p = 0.02$). In two small, randomized, crossover trials, dornase alfa provided a greater improvement in lung function, albeit at a much higher financial cost than IHS ($70/month). One approach is to consider the use of IHS in patients who are intolerant or do not respond to a trial of dornase alfa. In addition, IHS should be considered as add-on therapy in patients with airway congestion despite optimal standard therapy (i.e., dornase alfa and chest physiotherapy). A short-acting β_2-agonist should be given before IHS treatment because IHS has been associated with bronchospasm.[78] IHS is available commercially, and its use is recommended to improve lung function and reduce exacerbations in all patients 6 years of age or older.[70] If clinical symptoms warrant additional intervention, IHS may be considered for preschool children as well (Infant and pending preschool guidelines).

Bronchodilation

The chronic use of inhaled β_2-agonists improves lung function in patients with bronchial hyperresponsiveness or a positive bronchodilator response, and is recommended for use.[70] In addition, they may assist in airway clearance when administered before chest physiotherapy. No clear consensus exists for the use of other bronchodilators. Studies in support of inhaled anticholinergic medications for the treatment of CF also are limited, and the results have been mixed.[79]

CASE 21-2

QUESTION 1: J.P. is a 12-year-old girl who was seen for a routine quarterly visit at the CF center. J.P. was diagnosed with CF at age 7 months as a result of failure to thrive. Genotyping revealed she is homozygous for ΔF508. At this visit she has complaints of increased cough and chest congestion when compared with her visit 3 months ago. She has a history of hemoptysis, but has not had an episode recently. She has had no pulmonary exacerbations in the last 12 months. Her current medications include pancreatic enzymes (approximately 2,000 units of lipase/kg/meal) with all meals, a fat-soluble vitamin supplement, two puffs of albuterol inhaler before airway clearance treatment once daily, dornase alfa 2.5 mg via nebulization once daily, and fluticasone 44 mcg inhaler two puffs daily. She performs airway clearance using HFCWO for 30 minutes once daily and reports she is tolerating this therapy well. Microbiological cultures of her oropharyngeal tract grow S. aureus; she has not grown P. aeruginosa in the past. J.P.'s body mass index is in the 60th percentile (stable from last visit), and her lung function tests show an FEV_1 of 1.99 L (89% predicted), which is down from her baseline of 2.05 L (92% predicted). A recent chest computed tomography revealed mild bronchiectatic changes in all lobes as well as mucus plugging and air trapping. What steps should be taken to improve J.P.'s airway clearance?

Methods of mechanical assistance to remove pulmonary secretions are all equally effective, and the decision about which device to use should be individualized. J.P. is currently using HFCWO and appears to be tolerating this well. One advantage to this treatment is the independence it provides when compared with manual percussion and drainage, which requires the assistance of another individual. It is also efficient because the patient can perform some nebulization treatments while on the therapy vest (e.g., hypertonic saline).[70] This is especially an important consideration to improve adherence. The typical frequency and duration of treatment with HFCWO is 30 minutes twice daily. J.P. is currently using the therapy vest only once daily and could benefit from increasing the frequency of treatment to twice daily.

Dornase alfa improves sputum viscosity in patients with CF and provides benefit early in the course of the lung disease.[80] In the Pulmozyme Early Intervention Trial, the risk of pulmonary exacerbations was reduced by 34% in young patients with mild lung function abnormalities, and pulmonary function tests improved even in patients with close to normal pulmonary function. J.P. is currently receiving dornase alfa and should continue on this therapy to improve pulmonary function and reduce the risk of pulmonary exacerbations.

Hypertonic saline (7%) twice daily should also be considered for J.P. to enhance the mucociliary clearance and improve pulmonary function. The albuterol should be increased to twice daily to provide bronchodilation to prevent potential bronchospasm from the hypertonic saline. The recommended sequence of the treatments is albuterol for bronchodilation, hypertonic saline to hydrate the airways, and dornase alfa to liquefy the mucus, followed by airway clearance therapy to clear the mucus.[70] If adherence is an issue, the hypertonic saline can be administered during airway clearance treatment.

Control of Inflammation

The inflammatory response in CF airways contributes significantly to destruction of the airways and eventual pulmonary function decline. Pharmacological intervention to block the intense neutrophilic inflammatory response is a key strategy to reducing pulmonary disease progression. Corticosteroids, nonsteroidal anti-inflammatory drugs, and macrolides have all been used to control the inflammation seen in CF lung disease. Although leukotriene modifiers have improved lung function in small studies, the overall data are insufficient to support a recommendation for their use.[81] Cromolyn use is also not routinely recommended because of limited evidence of positive outcomes with this drug.[70]

CASE 21-2, QUESTION 2: Is J.P. a candidate for anti-inflammatory therapy?

CORTICOSTEROIDS

Oral corticosteroids are not recommended in the treatment of CF. Although prednisone 1 to 2 mg/kg every other day demonstrated a significant reduction in decline of lung function and decreased pulmonary exacerbations in patients with Pseudomonas infections, long-term use was associated with unacceptable adverse effects including cataracts, glucose intolerance, osteoporosis, and persistent growth retardation.[82–84] Although inhaled corticosteroids are widely prescribed to patients with CF, there are limited data supporting their use in this population. In particular, a randomized, controlled trial of withdrawal of inhaled corticosteroids demonstrated no change in pulmonary function after discontinuation; therefore, they are not recommended for routine use in patients with CF in the absence of concomitant asthma.[70,85] Fluticasone should be discontinued in J.P., and pulmonary function testing should be performed at the next clinic visit. In addition, J.P. should be questioned about wheezing or shortness of breath.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Nonsteroidal anti-inflammatory drugs have been used to slow lung function decline. High-dose ibuprofen (20–30 mg/kg twice daily with doses titrated to a peak concentration of 50–100 mg/L) can significantly slow the annual rate of FEV_1 decline in children between 5 and 13 years of age.[86] Ibuprofen serum concentrations must be measured and monitored closely to stay in the therapeutic range because lower concentrations can paradoxically increase neutrophil infiltration. Because these doses are much higher than the recommended doses to treat pain or fever, concerns about long-term side effects, including gastrointestinal bleeding and renal toxicity, together with the need for frequent blood draws have not made this method of treatment common. For patients at least 6 years of age with an FEV_1 greater than 60% of predicted, chronic oral ibuprofen is recommended to reduce the loss of lung function.[70] Considering J.P.'s history of hemoptysis, the use of high-dose ibuprofen is not recommended.

AZITHROMYCIN

Azithromycin is an antibiotic with anti-inflammatory properties. Although its use is established in patients with CF with chronic P. aeruginosa infection (see Case 26-3, Question 3), a recent study conducted in children and young adults who were not infected with P. aeruginosa demonstrated a significant reduction in exacerbation frequency (50%) and increased weight (0.58 kg) during the 24-week study period; however, no improvement in pulmonary function was noted.[87]

Because J.P. has not experienced any pulmonary exacerbations during the past year, there would be little advantage to adding azithromycin unless she becomes chronically infected with P. aeruginosa.[70]

ANTIBIOTIC THERAPY

Treatment of pulmonary infections in patients with CF has undoubtedly contributed to the improved survival observed in patients with CF in the past 30 years. Antibiotics are indicated in patients with CF for (a) early eradication of P. aeruginosa at the time of first detection with the intent to prevent or delay chronic infection, (b) treatment of acute pulmonary exacerbations, and (c) chronic maintenance therapy with inhaled antibiotics to control the bacterial burden within the airways with the goal of slowing the progression of pulmonary function decline.

Early Eradication of Pseudomonas Aeruginosa

CASE 21-2, QUESTION 3: J.P. returns to clinic 6 weeks later for a follow-up visit to evaluate response to changes made at the previous visit. Subjectively, she reports less chest congestion and cough. Spirometry demonstrates her FEV_1 has returned to baseline. A throat culture is obtained and reveals P. aeruginosa. What additional therapies should be considered for J.P. at this time?

Because of the increased rate of pulmonary function decline and shortened survival in patients chronically infected with P. aeruginosa, early treatment with the goal of eradication is recommended.[70] Results of two studies provide guidance on the optimal treatment approach. The Early Inhaled Tobramycin for Eradication trial demonstrated that treatment with inhaled tobramycin 300 mg twice daily for 28 or 56 days was similar in terms of eradication at 1 month (93% vs. 92%) and time to recurrence of P. aeruginosa (66% vs. 69% culture free at 27 months).[88] The Early Pseudomonas Infection Control trial demonstrated that therapy (inhaled tobramycin 300 mg twice daily for 28 days with or without ciprofloxacin twice daily for 14 days) initiated when quarterly respiratory cultures are positive for P. aeruginosa was not different in eradication or recurrence when compared with a similar antibiotic regimen cycled for 28 days followed by 56 days off for a period of six quarterly cycles.[89] Alternatively, results from a recent study conducted with aerosolized aztreonam 75 mg 3 times daily for 28 days in children older than 6 years with CF demonstrated eradication in 89.1% at the end of treatment and 58.2% remained culture negative at 28 weeks.[90] Based on the results of these two studies, it would be appropriate to start J.P. on inhaled tobramycin 300 mg twice daily or aztreonam 75 mg 3 times daily for 28 days. Cultures should be obtained on completion of the therapy to confirm eradication and quarterly thereafter to monitor for recurrence of P. aeruginosa.

Acute Pulmonary Exacerbation

Acute pulmonary exacerbations are an inevitable consequence of pulmonary disease in most patients with CF. A pulmonary exacerbation is defined as a change in respiratory signs and symptoms from the patient's baseline that necessitates treatment with antibiotics and augmented airway clearance. Key indicators include increased cough or sputum production, decreased exercise tolerance, loss of weight or appetite, decrease in FEV_1 or forced vital capacity (FVC) by more than 10%, or onset of new or increased crackles.[91] Approximately one-third of patients experience at least one pulmonary exacerbation annually; however, the onset and frequency varies widely in the population. The frequency of exacerbations is correlated with severity of pulmonary disease. Traditional management for an acute CF exacerbation includes nutritional repletion, antibiotics, and chest physiotherapy.[92] For mild exacerbations the patient can typically be managed in the outpatient setting using oral antibiotics and an intensification of airway clearance and nutritional therapies. For moderate to severe exacerbations, patients are typically hospitalized and receive a 14-day course of intravenous (IV) antibiotics, as well as airway clearance and nutrition therapies. If the patient demonstrates a significant improvement in signs and symptoms, he or she may be a candidate to complete treatment at home before completion of the 14-day course.[93]

ANTIBIOTIC DRUG SELECTION

Antibiotic drug selection is based on sputum or throat culture and susceptibility data. Combination therapy with two antibiotics with different mechanisms of action is often prescribed for treating acute pulmonary exacerbations involving P. aeruginosa to prevent the development of resistance and provide potential synergistic activity. Therefore, the combination of an antipseudomonal β-lactam and an aminoglycoside or fluoroquinolone is frequently used. Results of a controlled trial comparing β-lactam monotherapy versus β-lactam plus an aminoglycoside demonstrated similar improvement in pulmonary function, but greater reduction in bacterial density in sputum and a longer duration before readmission for a new pulmonary exacerbation in the patients receiving combination therapy.[94] Multidrug-resistant strains, defined as resistance to all agents within two of the three major classes of antipseudomonal therapies (e.g., β-lactams, aminoglycosides, and fluoroquinolones), are reported in

15% to 20% of patients. Treatment of infections involving these organisms may require the use of IV colistimethate. The use of IV colistin requires close monitoring as this drug exhibits both neurotoxic and nephrotoxic effects.

ANTIBIOTIC DOSING

The antibiotics used most commonly to treat acute pulmonary exacerbations and their dosage ranges are listed in Table 21-4. Typical dosage regimens used in other populations may not be adequate in patients with CF owing to reduced lung penetration, decreased activity in sputum, presence of bacteria within biofilms, heavy inocula, and reduced susceptibility. Altered pharmacokinetics of drugs in patients with CF is also frequently cited in the published literature. In particular, both the volume of distribution and the clearance of a number of antibiotics (e.g., β-lactams and aminoglycosides) are reported to be higher in patients with CF when compared with healthy control subjects. Because many of the β-lactam antibiotics are cleared renally, it has been hypothesized that the enhanced renal clearance observed in patients with CF might be related to a higher tubular clearance as a result of upregulation of organic anion and cation transporters as a compensatory response to the CFTR defect.[95] However, subsequent controlled trials failed to confirm this hypothesis.[96,97] A more unifying explanation of the observed differences in pharmacokinetics in CF is related to differences in body composition. Patients with CF have reduced adipose tissue and lean mass owing to nutritional deficiencies. If the pharmacokinetic parameters are normalized to body weight (e.g., L/kg and L/kg/hour), then the parameters would appear to exceed that of normal healthy individuals. This observation was recently demonstrated in a clinical trial evaluating the pharmacokinetics of ceftazidime in CF. The intersubject variability in pharmacokinetic parameters was significantly reduced when the parameters were normalized to fat-free mass, indicating that fat-free mass is a better metric for normalization.[98] Importantly, the authors observed that the pharmacokinetic parameters appeared higher when normalized to body weight; however, when normalized to fat-free mass, there was no significant difference.

Table 21-4

Antibiotic Doses for Cystic Fibrosis

Systemic Antibiotics			
Drug	**Pediatric Dose**	**Adult Dose**	**Maximum Daily Dose**
Amikacin	30 mg/kg q24h	30 mg/kg q24h	TDM
Aztreonam	150 mg/kg/day divided q6-8h	2 gm q6h	8 g/day

Cefepime	150 mg/kg/day divided q6–8h	2 gm q6h	8 g/day
Ceftazidime	150 mg/kg/day divided q6–8h	2 gm q6h	8 g/day
Ciprofloxacin IV	30 mg/kg divided q8h	400 mg q8h	1.2 g/day
Ciprofloxacin PO	40 mg/kg divided q8-12h	750 mg q8–12h	2.25 g/day
Colistimethate	2.5–5 mg/kg/day divided q8h	2.5–5 mg/kg/day divided q8h	300 mg/day colistin base
Gentamicin	10 mg/kg q24h	10 mg/kg q24h	TDM
Imipenem	100 mg/kg/day divided q6h	1 g q6h	4 g/day
Meropenem	60–120 mg/kg/day divided q8h	2 g q8h	6 g/day
Piperacillin/tazobactam	400 mg/kg/day divided q6h	4.5 g q6h	16 g/day (piperacillin)
Ticarcillin/clavulanate	400 mg/kg/day divided q6h	3 g q6h	12 g/day (ticarcillin)
Tobramycin	10 mg/kg q24h	10 mg/kg q24h	TDM
TMP/SMZ	15–20 mg/kg/day divided q8h	15–20 mg/kg/day divided q8h	800 mg/day
Inhaled Antibiotics			**Comments**
Drug	**Dosage (mg)**	**Interval**	
Aztreonam	75	TID	28 days on, 28 days off
Tobramycin nebulized	300	BID	28 days on, 28 days off
Tobramycin Podhaler	112 (4 × 28 mg capsules)	BID	28 days on, 28 days off
Colistin	37.5–75	BID	28 days on, 28 days off

BID, 2 times daily; TDM, therapeutic drug monitoring (gentamicin/tobramycin desired maximal concentration is 25–35 mg/L, AUC_{24h} = 70–100 mg/L × hour; once-daily dosing); TID, 3 times daily; TMP/SMZ, trimethoprim/sulfamethoxazole.

Adapted from Zobell et al. Optimization of anti-pseudomonal antibiotic for cystic fibrosis pulmonary exacerbations: VI. Executive summary. Pediatr Pulmonol. 2013;1.

β-Lactam antibiotics can be administered as an intermittent, prolonged, or continuous infusion. Prolonged or continuous infusion are designed to maximize the time the concentrations exceed the minimum inhibitory concentration.[98] This is particularly important in patients with CF because of the rapid clearance (excellent renal function) and reduced susceptibility of the organisms within the airways.[99]

Extended-interval dosing of aminoglycosides (every 24 hours compared with every 8 hours) is easier and less costly to administer, and potentially limits toxicity. A randomized clinical trial in children and adults with CF (n = 244) demonstrated equivalent efficacy as evidenced by a change in FEV_1 in approximately 10% in patients receiving tobramycin 10 mg/kg/day either as a single dose or in three divided doses. However, the once-daily regimen provided improved renal safety in children as evidenced by serum creatinine and urinary N-acetyl-β-D-glucosaminidase, a biomarker of renal proximal tubular injury.[100] An evidence-based review conducted by the Cystic Fibrosis Foundation concluded that once-daily dosing of aminoglycosides is preferable to 3 times–daily dosing for treatment of an acute exacerbation of pulmonary disease.[93]

Routine monitoring of serum aminoglycoside concentrations is recommended to maximize efficacy and minimize the risk of toxicity. Because many patients with CF receive multiple courses of aminoglycosides, sometimes for extended durations, they are particularly predisposed to the toxicities. With once-daily dosing the trough concentrations are expected to be unmeasureable by design (e.g., dosing interval exceeds 5 half-lives). Therefore, serum concentrations are typically obtained between 1 to 2 and

---

6 to 8 hours after the end of the infusion. The two levels can then be used to determine the extrapolated peak concentration (target 20–30 mg/L) and the area under the serum concentration–time curve (target 72–100 mg/L × hour).[101]

CASE 21-3

QUESTION 1: B.W., a 19-year-old man, was diagnosed with CF at 3 years of age after a history of chronic pneumonias. He presents to the pulmonary clinic with increasing cough and sputum production during the past 2 weeks, with a change in sputum color from white to green. He was last admitted for treatment of an acute pulmonary exacerbation 6 months ago. He currently weighs 45.2 kg and states he has lost 4 pounds. B.W. is a slightly thin adult man whose breathing is labored. Pulmonary function tests reveal an FEV_1 of 75% of predicted and an FVC of 70% (his usual baselines are FEV_1, 85%, and FVC, 80%). P. aeruginosa grew out of his sputum sample taken at the clinic 4 weeks ago and demonstrated susceptibility to ceftazidime, piperacillin, imipenem, tobramycin, and colistin, and intermediate susceptibility to ciprofloxacin. Other pertinent laboratory findings are as follows:

White blood cell count, 17,000/μL, with 4% bands, 35% segmented neutrophils, 50% lymphocytes, and 11% eosinophils
Blood urea nitrogen (BUN), 7 mg/dL
Creatinine, 0.5 mg/dL

All other blood work, liver function tests, and electrolytes are within normal limits. Heart rate and blood pressure are normal. Temperature is 99.2°F, respiratory rate is 25 breaths/minute with an oxygen saturation of 95%. A number of new pulmonary infiltrates are seen on chest radiograph. His current medications include the following: one fat-soluble vitamin twice daily, two microencapsulated pancreatic enzyme capsules (16,000 units of lipase/capsule) with meals, and one or two capsules with snacks as needed, and dornase alfa 2.5 mg nebulized daily. What subjective and objective findings does B.W. exhibit that would lead to the diagnosis of a pulmonary exacerbation?

B.W. demonstrates an increase in sputum production (purulent), increased cough, dyspnea, weight loss, and a 10% decline in pulmonary function tests from baseline. B.W. also has a mild fever and elevated white blood cell count; however, an increase in white blood cell count, fever, or appearance of a new infiltrate on chest radiograph may or may not be present in all cases of pulmonary exacerbations.

CASE 21-3, QUESTION 2: B.W. is admitted to the hospital for treatment of an acute pulmonary exacerbation. What would be an appropriate antimicrobial treatment plan for B.W. based on his current laboratory data?

Based on these findings and the in vitro susceptibility results, it would be reasonable to initiate a regimen of ceftazidime or piperacillin in combination with tobramycin. Ciprofloxacin is not optimal in this instance because of reduced susceptibility. Imipenem and colistin are typically reserved for treatment of resistant P. aeruginosa infections.

Ceftazidime 2 g IV every 6 hours could be administered to B.W. by intermittent, 3 hour prolonged infusion, or a 2 g loading dose administered for 30 minutes followed by 6 g as a continuous infusion. Recent data from a large randomized trial demonstrated similar efficacy and safety between intermittent and continuous infusion ceftazidime in patients with CF; however, the continuous infusion treatment was associated with greater improvement in pulmonary function in those infected with resistant strains. In addition, continuous infusion resulted in a significantly prolonged interval between exacerbations.[99]

In B.W., the preferred initial dosing regimen of IV tobramycin would be 440 mg (10 mg/kg) every 24 hours. Target peak concentrations of 20 to 30 mg/L should be verified after the first or second dose. Target area under the concentration–time curve should be 72 to 100 mg/L × hour. Tobramycin concentrations should be measured at least every 7 days while B.W. is on therapy. In addition, serum concentrations of BUN and creatinine should be measured 3 times weekly for early detection of acute kidney injury.

The antibiotics should be administered for 2 weeks, and extended for an additional 7 days if B.W. fails to reach specified end points at day 14. After the initiation of antibiotics in this hospitalization, home IV antibiotic therapy should be a consideration for B.W.[102] The decision as to whether a patient is a good candidate for home IV antibiotic therapy is based on initial response as well as the expected level of support provided to the patient at home. In particular, the ability of the patient to maintain nutritional and intensive airway clearance programs established in the hospital needs to be assessed. The duration of B.W.'s antibiotic therapy should be based on his clinical response. Ideally, his pulmonary function (e.g., FEV_1) should improve by 10% to 20% and should be evaluated weekly. The purulent nature and volume of the sputum should decrease and a gradual overall improvement in subjective feeling should be noted. Improved appetite and increased weight gain should be assessed daily with the goal of reaching baseline weight (increase of 1–2 kg/week). For patients receiving repeated courses of IV aminoglycosides, periodic audiometric testing is recommended.

CHRONIC MAINTENANCE THERAPY WITH ORAL OR INHALED ANTIBIOTICS

Recognition of the progressive decline in pulmonary function despite aggressive treatment of acute exacerbations and the availability of oral and inhaled therapies with activity against typical CF pathogens have led to increased use of chronic maintenance antibiotic therapy. The goal of chronic maintenance therapy is to suppress bacterial infection to reduce the frequency and severity of pulmonary exacerbations and to slow the progressive deterioration in lung function. Inhaled antibiotics include tobramycin, aztreonam, and colistimethate. Inhaled antibiotics are desirable because of the relatively high sputum concentrations and low systemic bioavailability, which maximizes efficacy and minimizes toxicity.

Tobramycin for Inhalation

Results of phase 3 studies of inhaled tobramycin conducted during a 6-month interval demonstrated significant improvement in pulmonary function (relative difference in FEV_1 of 10%), a reduction in the risk of hospitalization (37%), and a reduced need for IV antipseudomonal antibiotics (32%).[103] A significantly greater proportion of patients in the treatment arm reported hoarseness; however, this did not require discontinuation and improved with time. In addition, some patients report a bitter taste to this preparation; however, this typically does not result in discontinuation of the medication. The recommended dosage of tobramycin nebulizer solution is 300 mg twice daily in a cycle of 28 days on and 28 days off. Tobramycin for inhalation is provided as a premixed solution contained in unit dose vials and requires refrigeration before use. Tobramycin for inhalation is administered via a vented jet nebulizer system (Pari LC Plus) to ensure consistent particle size and outflow characteristics. Based on the results of the phase 3 studies, inhaled tobramycin is indicated in patients older than 6 years of age with repeated sputum cultures demonstrating P. aeruginosa and FEV_1 between 25% and 75% of predicted.[70] Fortunately, there is a dry powder formulation of tobramycin for inhalation (TOBI podhaler) which offers the advantages of shortened administration time, no need for refrigeration, and easy portability. TOBI podhaler is provided

---

in 28 mg capsules and is administered as four capsules twice daily in a cycle of 28 days on and 28 days off.

Aztreonam Lysine Solution for Inhalation

Two phase 3 trials evaluated the short-term safety and efficacy of aztreonam lysine solution for inhalation.[103,104] The results of these trials demonstrated a significant improvement in respiratory symptoms assessed using a patient-reported outcome instrument, and a significant delay in the need for inhaled or IV antipseudomonal antibiotics determined by the presence of pulmonary exacerbation symptoms. The most common adverse effects are cough and wheezing. Bronchodilator use is recommended before each dose to reduce these symptoms. The recommended dosage of aztreonam lysine is 75 mg 3 times daily for 28 days. Aztreonam is provided in a powder form that requires reconstitution with saline before administration. Aztreonam requires refrigeration before use. A special nebulizer device is required for administration (Altera), which delivers the drug in a relatively short time (e.g., 2–3 minutes). Based on the results of these studies, aztreonam lysine is indicated in CF patients older than 6 years of age with P. aeruginosa to improve respiratory symptoms. Aztreonam is particularly useful in patients who are intolerant of inhaled tobramycin, or as add-on therapy in those with frequent exacerbations or continued decline in pulmonary function.

Colistimethate

Colistimethate is a prodrug of colistin, an antibiotic in the polymyxin family. Colistimethate is available only in an IV powder formulation in the United States and requires reconstitution before nebulization. Clinical trials evaluating the safety and efficacy of colistimethate in CF are limited by the small number of patients enrolled in the trials. Based on the lack of data, colistimethate is not recommended for routine use.[70] Colistimethate may be useful in patients infected with multidrug-resistant P. aeruginosa or those intolerant to other inhaled antibiotics. Adverse effects associated with inhaled colistimethate include cough and bronchospasm. Bronchodilators should be used before each dose. In addition, colistimethate tends to foam on nebulization, resulting in incomplete drug administration. The typical dose of colistimethate is 75 mg twice daily.

The cost of inhaled antibiotics is relatively high (tobramycin solution for inhalation $7,000/month, aztreonam lysine solution for inhalation $7,000/month, colistimethate $1,800/month (**http://www.walgreens.com/topic/pharmacy/cystic-fibrosis-services.jsp**); however, use of inhaled antibiotics reduces hospital days, leading to substantial savings in direct medical costs that may offset its acquisition price. The cost-effectiveness of inhaled antibiotics would be expected to be greatest in patients experiencing relatively frequent exacerbations (two or more hospital admissions per year). A short-term trial (e.g., 1–2 months) is warranted in patients with CF chronically colonized with P. aeruginosa to assess improvement in pulmonary function. A longer trial period (e.g., up to 1 year) may be necessary to assess the impact on hospitalizations. Patients should be instructed in the proper use and maintenance of the nebulizer and compressor system used in its delivery. In particular, it is important to wash reusable nebulizers between uses to avoid buildup that can reduce their effectiveness. The nebulizers can be hand-washed with liquid dish soap or placed in the top rack of a dishwasher for cleaning. After each cleaning the nebulizer should be allowed to dry before reusing to reduce bacterial contamination. Regular sterilization is required to reduce the potential for bacterial contamination. In addition, the patient should be instructed not to dilute or mix antibiotic solutions with other drugs in the nebulizer, which can alter the delivery characteristics. Inhaled antibiotics are typically administered after the bronchodilator, dornase alfa, and airway clearance therapies to maximize retention time within the airways.

Azithromycin

Oral azithromycin is frequently prescribed to patients with CF owing to its anti-inflammatory and antivirulence properties. The macrolide antibiotics do not exhibit significant antibacterial activity against P. aeruginosa using conventional susceptibility testing methods; however, they do inhibit alginate production, the principal component of biofilms. Because of its favorable pharmacokinetics and reduced potential for drug interactions, most studies have evaluated azithromycin. Results of a multicenter randomized, controlled trial demonstrated treatment with azithromycin was associated with a significant improvement in FEV_1 (6%) and a reduction in hospitalizations for acute pulmonary exacerbations (44%).[105] The beneficial effect of azithromycin on pulmonary function was additive with other chronic therapies such as aerosolized tobramycin and dornase alfa. Azithromycin is generally well tolerated. Nausea, vomiting, and wheezing are the most common adverse effects reported. Based on current data, azithromycin is indicated in patients older than 6 years who are colonized with P. aeruginosa.[95] Based on the pivotal trial, the dose of azithromycin is 500 mg 3 times/week for patients weighing more than 40 kg and 250 mg 3 times weekly for patients weighing less than 40 kg. One contraindication to treatment with azithromycin is colonization with mycobacteria because of the potential for development of resistance.

CASE 21-3, QUESTION 3: B.W. comes to the outpatient clinic 2 weeks after hospital discharge for a follow-up visit and reports a significant reduction in cough and sputum production, and no shortness of breath. Spirometry reveals an FEV_1 of 85% of predicted. He has resumed his outpatient treatment regimen, which includes one multiple vitamin every day, two microencapsulated pancreatic enzyme capsules (16,000 units of lipase/capsule) with meals, and one or two capsules with snacks as needed, and dornase alfa 2.5 mg nebulized daily. What changes, if any, should be made to B.W.'s treatment regimen?

Because B.W. has had two exacerbations in the last 6 months, he would benefit from the addition of medications to reduce the frequency of exacerbations. In addition to the disruption to his life, frequent exacerbations are associated with more rapid decline in pulmonary function and reduced survival.[106] Key pharmacological therapies demonstrated to improve pulmonary function and reduce the frequency of pulmonary exacerbations include dornase alfa, inhaled tobramycin or aztreonam, IHS, and azithromycin. B.W. is already receiving dornase alfa, but is not on inhaled tobramycin or aztreonam, IHS, or azithromycin. One important consideration when adding new therapies is the treatment burden, particularly with inhaled therapies. Inhaled tobramycin 112 mg twice daily via the podhaler cycled for 28 days on and 28 days off and oral azithromycin 500 mg every Monday, Wednesday, and Friday would be appropriate additions to the treatment regimen because B.W. is chronically infected with P. aeruginosa, and these particular agents demonstrated the greatest improvement in pulmonary function when compared with IHS. In addition, azithromycin has a minimal effect on treatment burden as it can be administered orally 3 days a week. IHS would also be of benefit by reducing exacerbation frequency; however, it could be added in the future if B.W. demonstrates a decline in pulmonary function or increased frequency of exacerbations despite the new additions.

Oral Antibiotics

CASE 21-3, QUESTION 4: One year later, B.W. returns to the clinic exhibiting signs and symptoms of a mild exacerbation, but refuses IV antibiotics or hospitalization because he is in the middle of final examinations. What alternative to IV therapy is available to treat B.W.?

The quinolone family of antibiotics is currently the only option for oral treatment of P. aeruginosa. Emergence of resistant strains of Staphylococcus and Pseudomonas species have led the CF medical community to restrict the use of quinolones to the treatment of acute CF exacerbations.[107,108] Oral fluoroquinolones (e.g., ciprofloxacin) have become widely used in patients with CF because they are less expensive, easy to administer, and as effective as IV therapy in an acute exacerbation.[109,110]

Because of the past sensitivities of B.W.'s organisms and his refusal to be admitted to the hospital, ciprofloxacin 1,000 mg orally twice daily for 1 week can be initiated in addition to the aerosolized tobramycin and oral azithromycin.[111] After 1 week of the combined aerosol and oral therapies, B.W. should be re-evaluated for hospital admission if his condition worsens, or his therapy can be continued if his condition improves.

CASE 21-3, QUESTION 5: B.W. returns to the outpatient clinic 3 months later for his annual comprehensive visit. Results of laboratory studies, dual-emission x-ray absorptiometry (DXA) scan, spirometry, and an oral glucose tolerance test (OGTT) are as follows:

BUN, 10 mg/dL
Creatinine, 0.6 mg/dL
Urine microalbumin/creatinine, 12 mcg/mg
2-hour OGTT plasma glucose, 220 mg/dL
Glycosylated hemoglobin, 7.8%
DXA Z-score, −2.1 (pelvis)
FEV_1, 83% of predicted

How should these laboratory studies be interpreted and what new therapies would you recommend?

The elevated 2-hour OGTT plasma glucose indicates B.W. has CF-related diabetes mellitus. This is confirmed by the elevated glycosylated hemoglobin. The urine microalbumin testing indicates that B.W. is not spilling protein into the urine as a result of the CF-related diabetes mellitus. Treatment with insulin should be initiated in B.W. to improve nutritional status and prevent microvascular complications. The DXA scan results indicate B.W. has osteopenia and should be initiated on calcium 500 mg orally twice daily and his vitamin D status should be determined. Treatment of osteopenia is recommended to prevent progression to osteoporosis, which would put the patient at risk for fractures. In addition, osteoporosis is a relative contraindication for lung transplantation because of the risk for fractures after transplantation that may impair adequate recovery.

B.W.'s spirometry results indicate that his pulmonary function is stable and his current pharmacotherapeutic regimen should be continued.

LUNG TRANSPLANTATION

Pulmonary disease progression leading to eventual respiratory failure is an inevitable consequence of the chronic cycle of airway obstruction, infection, and inflammation. End-stage lung disease (defined by an FEV_1 of <30% of predicted) significantly affects the quality of life for patients with CF as a result of reduced exercise tolerance, heavy treatment burden, need for oxygen therapy, and frequent hospitalizations for pulmonary exacerbations. Lung transplantation is a potential therapeutic option for CF patients with end-stage lung disease.[112] The optimal time to refer a patient for lung transplantation is not precisely defined; however, patients are typically referred when their FEV_1 is approximately 40% to maximize the chances of obtaining new lungs before the patient experiences respiratory failure. Transplant evaluation includes assessments of pulmonary disease severity, patient adherence to therapies, and concomitant illnesses. Once accepted into the program, the patient is placed on the transplant list awaiting availability of potential organs. The waiting time to receive a lung transplant is highly variable and depends on the Lung Allocation Score, a score that distributes organs on the basis of model-predicted benefit from transplantation. The mean survival after lung transplantation is approximately 50% at 5 years. Importantly, the quality of life for many lung transplant recipients improves significantly.

Nausea and Vomiting

Lisa M. DiGrazia and Joseph Todd Carter

CORE PRINCIPLES	CHAPTER CASES
MOTION SICKNESS	
① Motion sickness is caused by discordant information about body position or motion received from visual, vestibular, or body proprioceptors. Acetylcholine is thought to be the primary neurotransmitter involved.	**Case 22-1 (Question 1)**
② Transdermal scopolamine is recommended for prophylaxis of motion sickness for moderate to severe stimuli. Dimenhydrinate or promethazine is recommended for treatment of breakthrough symptoms. The most common adverse effects of these agents include drowsiness, confusion, and dry mouth.	**Case 22-1 (Question 2), Table 22-1**
CHEMOTHERAPY-INDUCED NAUSEA AND VOMITING	
① Nausea and vomiting are initiated by several stimuli and mediated by several neurotransmitters in the central nervous system, peripheral nervous system, and gastrointestinal tract. Because of the multiple neurotransmitter receptors involved, successful prophylaxis and treatment of chemotherapy-induced nausea and vomiting will almost always require medications with more than one mechanism of action.	**Case 22-2 (Question 1)**
② The likelihood of nausea and vomiting depends on patient risk factors and, most importantly, on the emetogenicity of the chemotherapy agents prescribed. The antiemetic regimen should be appropriate for the chemotherapy agent with the highest emetogenicity level.	**Case 22-2 (Question 1), Table 22-2**
③ Patients receiving moderate to highly emetogenic chemotherapy should receive prophylaxis with an aprepitant-, netupitant-, or olanzapine-containing regimen. The backbone of these regimens includes a 5-hydroxytryptamine receptor type 3 (5-HT_3) antagonist and dexamethasone.	**Case 22-2 (Question 2), Tables 22-3, 22-4, Figures 22-2, 22-3**
④ For breakthrough symptoms, patients should receive rescue antiemetics with a different mechanism of action than the prophylactic medications and receive more aggressive antiemetics before the next cycle of chemotherapy.	**Case 22-2 (Question 3), Tables 22-3, 22-4, Figures 22-2, 22-3**

RADIATION-INDUCED NAUSEA AND VOMITING

1	Radiation can cause nausea and vomiting by the same pathways as chemotherapy. The risk depends on the area and size of the radiation field as well as the fractional dose of radiation and whether the patient has had chemotherapy in the past.	**Case 22-3 (Question 1), Table 22-5**
2	The recommended prophylaxis for radiation-induced nausea and vomiting includes a 5-HT_3 antagonist with dexamethasone for high-risk patients and with or without dexamethasone for patients at moderate risk. Breakthrough symptoms may be treated with a 5-HT_3 antagonist or dopamine antagonist.	**Case 22-3 (Question 1), Table 22-5**

POSTOPERATIVE NAUSEA AND VOMITING

1	The risk of postoperative nausea and vomiting depends on several patient-related, surgical, and anesthetic factors. The antiemetic regimen should be proportional to the risk factors.	**Case 22-4 (Question 1), Table 22-6**
2	The most active agents in preventing postoperative nausea and vomiting are 5-HT_3 antagonists. For patients at moderate to high risk, a 5-HT_3 antagonist should be combined with dexamethasone or droperidol. Antiemetics used for rescue therapy should be of a different class than the prophylactic agents used.	**Case 22-4 (Question 1), Table 22-6**

DEFINITION

Nausea and vomiting are unpleasant symptoms caused by self-limiting disorders or serious conditions such as cancer. These symptoms can range from mild, short-lived nausea to continuing severe emesis and retching. The emetic response can be described in three phases: nausea, vomiting, and retching. Nausea is the subjective feeling of the need to vomit. It includes an unpleasant sensation in the mouth and stomach and can be associated with salivation, sweating, dizziness, and tachycardia. Vomiting is the forceful expulsion of the stomach contents through the mouth but is preceded by the relaxation of the esophageal sphincter, contraction of the abdominal muscles, and temporary suspension of breathing. Retching is the rhythmic contraction of the abdominal muscles without actual emesis. It can accompany nausea or occur before or after emesis.

EPIDEMIOLOGY AND CLINICAL

PRESENTATION

Nausea and vomiting are caused by many disorders. Central nervous system (CNS) causes include increased intracranial pressure, migraine headaches, brain metastases, vestibular dysfunction, alcohol intoxication, and anxiety. Infectious disease causes include viral gastroenteritis, food poisoning, peritonitis, meningitis, and urinary tract infections. Metabolic causes include hypercalcemia, uremia, hyperglycemia, and hyponatremia. Gastrointestinal (GI) disorders, such as gastroparesis, bowel obstruction, distension, and mechanical irritation, can cause nausea and vomiting. Among the many medications that can cause nausea and vomiting are cancer chemotherapy, antibiotics, antifungals, and opiate analgesics.

In addition to the suffering involved, uncontrolled vomiting can lead to dehydration, electrolyte imbalances, malnutrition, aspiration pneumonia, and esophageal tears. Nausea and vomiting often reduces food intake and can impair a person's ability to care for himself or herself. Significant reductions in quality-of-life scores have been demonstrated in cancer patients with chemotherapy-induced nausea and vomiting (CINV) compared with patients who did not have those symptoms.[1]

PATHOPHYSIOLOGY

The CNS, the peripheral nervous system, and the GI tract are all involved in initiating and coordinating the emetic response. In the CNS, the vomiting center (VC) receives incoming signals from other parts of the brain and the GI tract, and then coordinates the emetic response by sending signals to the effector organs. The VC is located in the medulla oblongata of the brain, near the nucleus tractus solitarius (NTS). The VC is stimulated by neurotransmitters released from the chemoreceptor trigger zone (CTZ), the GI tract, the cerebral cortex, the limbic system, and the vestibular system (Fig. 22-1). The major neurotransmitter receptors associated with the emetic response include serotonin (the 5-hydroxytryptamine type 3 [5-HT_3]) receptors, neurokinin 1 (NK1) receptors, and dopamine receptors. Other receptors involved include corticosteroid, acetylcholine, histamine, cannabinoid, gabaminergic, and opiate receptors. Many of these receptors are targets for antiemetic therapy.

In the CNS, the CTZ is located in the area postrema on the floor of the fourth ventricle in the brainstem; it lies outside the blood–brain barrier. When the CTZ senses toxins and noxious substances in the blood or cerebrospinal fluid, it triggers the emetic response by releasing neurotransmitters that travel to the VC and NTS. The major neurotransmitter receptors include serotonin, dopamine, and NK1.

The GI system also plays a large part in the initiation of the emetic response. The GI tract contains enterochromaffin cells in the GI mucosa. When these cells are damaged by chemotherapy, radiation, anesthetics, or mechanical irritation, serotonin is released, which can stimulate the vagal afferents as well as directly stimulate the VC and NTS. The VC then initiates the emetic response.

The cerebral cortex and limbic system can stimulate the emetic center in response to emotional states, such as anxiety, pain, and conditioned responses (anticipatory nausea and vomiting). The neurotransmitters involved in this pathway are less well understood. Disorders of the vestibular system, such as vertigo and motion sickness, stimulate the VC through acetylcholine and histamine release.

DIAGNOSIS

The initial evaluation of the patient with nausea and vomiting should include the onset of symptoms, the severity and duration of symptoms, hydration status, precipitating factors, current medical conditions and medications, and food and infectious contacts. The etiology of the nausea and vomiting should be determined, if possible, so that underlying conditions can be treated specifically. Supportive treatment should be initiated, if needed, including fluid and electrolyte replacement. If the nausea and vomiting is mild and self-limited, antiemetic therapy may not be required. For others, however, the appropriate antiemetic therapy will depend on the patient and the etiology of the nausea and vomiting.

MOTION SICKNESS

Clinical Presentation and Risk Factors

CASE 22-1

QUESTION 1: P.C. is a 27-year-old woman who has no significant medical history, with the exception of moderate dysmenorrhea and motion sickness associated with travel by air. Previously, she has taken dimenhydrinate before airplane trips with moderate success. She is engaged to be married, and she and her fiancé have decided on a weeklong Caribbean cruise for their honeymoon. P.C. is concerned that she may also develop sea sickness and that dimenhydrinate may not control her symptoms, particularly in the event of rough weather at sea. Will P.C. be at higher risk for motion sickness?

The symptoms of motion sickness occur in response to an unusual perception of real or apparent motion. In these situations, there is sensory conflict about body position or motion through the visual, vestibular, or body proprioceptors. Acetylcholine is thought to be the primary neurotransmitter involved in signaling the VC, as is histamine, but to a lesser extent. Adrenergic stimulation can block this transmission. Symptoms begin with stomach discomfort and progress to salivation changes, sweating, dizziness, lethargy, retching, and emesis. The risk of motion sickness is low in children younger than 2 years. The risk is highest in children and adolescents compared with adults, and higher in women than men. In some individuals, sensitivity to motion sickness diminishes with time.[2] Travel by boat is most likely to cause symptoms; air, car, and train travel is less likely to cause them.[3,4] Severity of the motion sickness is highly dependent on the individual and also varies with the weather and position in the plane or boat. Because of P.C.'s history and her travel plans, she is at high risk for recurrence of her motion sickness symptoms.

Nonpharmacologic Measures

CASE 22-1, QUESTION 2: What nonpharmacologic methods could PC employ to reduce her chance of developing motion sickness?

Nonpharmacologic measures or natural remedies may be useful for reducing motion sickness.[2] These include riding in the middle of the boat or plane, where the motion is less dramatic, lying in a semirecumbent position, fixing the vision on the horizon, avoiding reading, and closing the eyes if below deck or in the cabin. Many people recommend keeping active on a ship to "get their sea-legs" faster through habituation. The effectiveness of acupressure at the P6 point of the wrist (about three fingerbreadths above the wrist) is unclear. A controlled-stimulus trial compared two brands of wristbands with placebo; neither band was more effective than placebo in preventing symptoms of motion sickness.[5] Studies of ginger preparations also are equivocal. The action of ginger may be through enhanced gastric emptying and not on the vestibular system.[6,7]

Overview of Treatment

CASE 22-1, QUESTION 3: For P.C., what medications are available to prevent and treat motion sickness symptoms?

Anticholinergic agents and antihistamines that cross the blood–brain barrier effectively prevent and treat motion sickness.[3,4] In general, these medications are more effective in preventing than treating established symptoms. The 5-HT_3 receptor antagonists and NK1 receptor antagonists have not been shown to be effective in preventing motion sickness.[2,6] Nonsedating antihistamines are not as effective as other antihistamines because they do not sufficiently cross the blood–brain barrier.[2,3] Scopolamine has been well studied for the prevention of motion sickness and is highly effective.[2,8] In a controlled trial, scopolamine was more effective than promethazine, and both were more effective than placebo, meclizine, or lorazepam.[9] Scopolamine is available as a topical patch, which bypasses the problem of GI symptoms associated with motion sickness. Table 22-1 describes medications effective for motion sickness based on the intensity of the stimulus, adult doses, and potential adverse effects.

Table 22-1

Medications for Prevention or Treatment of Motion Sickness in Adults

Medication (Trade Name)	Dosage	Recommended Use	Adverse Effects
Scopolamine (Transderm-Scop)	1.5 mg TOP behind the ear every 3 days. Apply at least 3 hours (preferably 6–8 hours) before exposure.	Long-term exposure (>6 hours) to moderate to intense stimulus. Alternative treatment for shorter or milder stimulus.	Dry mouth, drowsiness, blurred vision, confusion, fatigue, ataxia
Dimenhydrinate (Dramamine)	50–100 mg PO every 4–6 hours (max 400 mg/day). May be taken PRN or on scheduled basis if required.	Short- or long-term exposure to mild to moderate stimulus. Alternative for intense stimulus.	Drowsiness, dry mouth, thickening of secretions, dizziness
Promethazine (Phenergan)	25 mg PO every 4–6 hours. May be taken	In combination with dextroamphetamine for	Drowsiness, orthostatic hypotension, dry mouth

	PRN or on scheduled basis if required. 25–50 mg IM every 4–6 hours for established severe symptoms. May be taken PRN or on scheduled basis if required.	short exposure to intense stimulus. Alternative for longer or milder stimulus.	
Meclizine (Dramamine Less Drowsy, Bonine)	12.5–50 mg PO every 6–24 hours. May be taken PRN or on scheduled basis if required.	Alternative for mild stimulus or in combination for moderate to severe stimulus.	Drowsiness, dry mouth, thickening of secretions, dizziness
Dextroamphetamine (Dexedrine)	5–10 mg PO every 4–6 hours. May be taken PRN or on scheduled basis if required.	In combination with promethazine for short exposure of intense stimulus.	Restlessness, abuse potential, insomnia, overstimulation, tachycardia, palpitations, hypertension

IM, intramuscular; PO, oral; PRN, as needed; TOP, topically.

Source: Priesol AJ. Motion sickness. In: UpToDate. http://www.uptodate.com/contents/motion-sickness. Accessed September 9, 2015; Shupak A, Gordon CR. Motion sickness: advances in pathogenesis, prediction, prevention, and treatment. Aviat Space Environ Med. 2006;77:1213.

Because P.C. is susceptible in a moderate to severe stimulus situation, prevention with a scopolamine patch applied behind the ear every 3 days, starting 6 to 8 hours before departure, should be recommended. If she experiences breakthrough symptoms, dimenhydrinate or promethazine may be useful. She should be advised about the potential adverse effects of these agents, which include drowsiness, confusion, and dry mouth.

CHEMOTHERAPY-INDUCED NAUSEA AND VOMITING

CINV occurs in many patients receiving chemotherapy for cancer.[1] The mechanisms of the emetic response described at the beginning of this chapter apply to CINV as well. The major neurotransmitter receptors involved in these pathways include 5-HT_3, NK1, and dopamine receptors. CINV can occur in different phases. Acute-phase CINV symptoms occur within a few hours after the administration of the chemotherapy. These symptoms often peak several hours after administration and can last for the first 24 hours. Some antineoplastic agents can also cause nausea and vomiting symptoms for a longer time after chemotherapy administration. These delayed CINV symptoms peak in about 2 to 3 days and can last 6 to 7 days. Some patients may experience acute symptoms without delayed symptoms or delayed symptoms without acute symptoms, whereas others experience CINV in both the acute and delayed phases. Some patients who have received previous chemotherapy treatments may experience a conditioned response in which they have symptoms even before the chemotherapy starts. This is called anticipatory nausea and vomiting and is difficult to treat because it is primarily triggered by poor nausea and vomiting control in previous cycles. Breakthrough nausea and vomiting occur if the primary prophylactic antiemetics fail to work completely. Of course, regardless of the time course and cause, these are very distressing, unpleasant, and disruptive symptoms for the patient.

The likelihood of CINV depends on several factors.[1] Patient-related factors that increase the risk of acute-phase CINV include age under 50 years, female sex, poor control of symptoms in prior cycles, history of motion sickness or nausea with pregnancy, anxiety, or depression. A significant history of alcoholism actually protects against CINV. Delayed symptoms are more common in women, in those who have had poor emetic control in the acute phase, and in patients with anxiety or depression.

Chemotherapy-related factors also predict the likelihood of symptoms. Factors such as shorter infusion time, higher dose, and more chemotherapy cycles increase the risk of CINV. With multiday chemotherapy regimens, the symptoms usually peak around the third to fourth day of chemotherapy, when the acute symptoms caused by the later days' doses are overlapping with the delayed symptoms from the first days' doses. The most predictive factor, however, is the chemotherapy agent's inherent ability to cause CINV, or its emetogenicity. [1,10,11] Antineoplastics that are most likely (>90% of patients) to cause symptoms are classified as highly emetogenic chemotherapy. Agents that cause nausea and vomiting in 30% to 90% of patients are classified as moderate-risk agents. Low emetogenicity agents cause symptoms in 10% to 30% of patients. Other chemotherapy agents have a minimal risk, causing CINV in less than 10% of patients. Table 22-2 lists selected chemotherapy agents in the various emetogenicity classes, noting that references differ in the estimation of emetic risk for some antineoplastic agents. The emetogenicity risk also depends on the dosage used and the route of administration.

Table 22-2

Emetogenicity of Selected Intravenous and Oral Antineoplastic Agents with Prophylaxis Options

Potential	Chemotherapy	Prophylaxis Options
Intravenous high emetic risk >90% frequency of emesis	AC combination defined as anthracycline (either doxorubicin or epirubicin) with cyclophosphamide Carboplatin AUC ≥4 Carmustine >250 mg/m^2 Cisplatin Cyclophosphamide >1,500 mg/m^2	Aprepitant-containing regimen OR Olanzapine-containing regimen OR

	Dacarbazine Doxorubicin ≥60 mg/m^2 Epirubicin >90 mg/m^2 Ifosfamide ≥2 g/m^2 per dose Mechlorethamine Streptozocin		Netupitant-containing regimen OR Rolapitant-containing regimen

Guideline update for MASCC and ESMO in the prevention of chemotherapy- and radiotherapy-induced nausea and vomiting: results of the Perugia consensus conference. Ann Oncol. 2010;21(Suppl 5):v232.

Certain antineoplastic agents are more likely to cause delayed CINV symptoms. These include cisplatin, carboplatin, cyclophosphamide, doxorubicin, epirubicin, ifosfamide, and, to a lesser degree, irinotecan and methotrexate. Patients receiving more than one of these agents are at high risk for delayed symptoms.

Most chemotherapy agents are given in combinations, rather than as single agents. Estimating the emetogenicity of chemotherapy combinations has always been difficult. The primary literature of the regimen should always be consulted to determine the emetic risk. Should that not be available, the antiemetic regimen should be geared toward the chemotherapy agent with the highest emetogenicity level given on that day.[1,12,13] For example, in a chemotherapy combination with one high-risk agent and one with a moderate risk, the antiemetic regimen should be appropriate for the high-risk chemotherapy agent.

Antiemetic efficacy, or complete emetic response, is usually defined as no emesis and no nausea or only mild nausea in the first 24 hours after chemotherapy administration. With currently recommended antiemetic regimens, most, but not all, patients will be protected from emesis in the acute phase (first 24 hours). Nausea, however, is more difficult to control. In addition, delayed CINV symptoms are more difficult to prevent.

Overview of Treatment

Appropriate antiemetic therapy is based on the emetogenicity of the chemotherapy regimen and patient risk factors. Because the pathophysiologic response of nausea and vomiting involves many neurotransmitters, combinations of antiemetics from different therapeutic classes will be more effective in most situations than a single agent. The predominant classes of antiemetics used for CINV include 5-HT_3 antagonists, the NK1 antagonist, and corticosteroids.

5-HT_3 ANTAGONISTS

The 5-HT_3 antagonists inhibit the action of serotonin in the GI tract and CNS, and thereby block the transmission of emetic signals to the VC. The 5-HT_3 antagonists are both highly effective and have minimal side effects. Several agents and dosage forms in this class are now available: ondansetron, granisetron, dolasetron, and palonosetron. Dosages of these agents are shown in Table 22-3. The route of administration should be matched to the clinical status of the patient. Oral tablets are appropriate for most patients, but intravenous (IV), topical, or oral dissolving tablet formulations may be needed in patients who cannot take oral medications.

These agents have been widely studied, and some commonalities have emerged. All of the 5-HT_3 antagonists are considered to have equivalent efficacy.[14–19] All of these agents have a threshold effect, and so a sufficiently large dose must be given to block the relevant receptors. In addition, the dose-response curve is relatively flat, such that escalating the dose beyond the threshold dose does not enhance efficacy. When given in appropriate doses, all of these agents have similar efficacy for acute CINV, with response rates of 60% to 80%, depending on study design.[1,12,14–19] The effectiveness of the 5-HT_3 receptor antagonists is enhanced by the addition of dexamethasone. The response rate increases by about 15% to 20% in regimens that include dexamethasone and a 5-HT_3 antagonist.[17,20] Oral and IV 5-HT_3 administration are equally effective assuming that the patient can take oral medications. The side effects of all the 5-HT_3 antagonists are similar and fairly mild and include headache, constipation, diarrhea, and transient elevations of liver function tests. The 5-HT_3 antagonists are one component of optimal antiemetic prophylaxis for acute CINV. However, they are not more effective than agents from other classes (notably dexamethasone, aprepitant, or prochlorperazine) for delayed CINV.[17,21–23] The 5-HT_3 antagonists, therefore, are not generally recommended for delayed CINV. The 5-HT_3 antagonists are metabolized by different cytochrome P-450 enzymes, including CYP1A2, CYP2D6, and CYP3A4. Differences in the metabolic rate of 5-HT_3 antagonists attributable to CYP2D6 polymorphisms might account for differences in efficacy among individual patients.[17] However, these differences are not used clinically to choose initial antiemetic therapy at this time.

Ondansetron, granisetron, and dolasetron have similar pharmacokinetic parameters. Palonosetron, the newest member of the 5-HT_3 antagonist family, is distinguished by a longer elimination half-life (approximately 40 hours) than others in its class.[24] One group of researchers described a three-drug combination of palonosetron, dexamethasone, and aprepitant in a noncomparative, phase II study with moderately emetogenic chemotherapy and found that the three-drug combination was safe and effective.[25]

Whether palonosetron is equivalent or superior to other 5-HT_3 antagonists should be determined by trials that compare palonosetron with another 5-HT_3 antagonist, with both treatment arms also containing dexamethasone and aprepitant in the acute and delayed phases. These trials have yet to be conducted. Currently, palonosetron is substantially more expensive than the generic forms of the other 5-HT_3 antagonists.

Palonosetron is normally administered as a single 0.25-mg IV before chemotherapy. Palonosetron has been studied in a three-dose regimen (administration on days 1, 3, 5) for multiday chemotherapy in an uncontrolled trial.[26] This regimen appeared to be safe and effective but was not compared with any other regimen. It is not clear that palonosetron would have superior activity compared with repeated doses of the other 5-HT_3 antagonists. In addition, palonosetron is given orally in combination with netupitant (see section on Neurokinin 1 Receptor Antagonist).

It is difficult to identify the 5-HT_3 antagonist with the highest overall cost-effectiveness because drug acquisition costs vary between the inpatient and outpatient clinics and from institution to institution. Costs of the different agents should be compared at each practice site to determine the preferred agent.

CORTICOSTEROIDS

The mechanism of action of corticosteroids as antiemetics has not been fully determined. Some suggest that corticosteroids may decrease serotonin release, antagonize 5-HT_3, or activate corticosteroid receptors in the NTS of the medulla in the CNS.[20] Many studies validate the effectiveness of corticosteroids in the prophylaxis of CINV symptoms. Efficacy with both dexamethasone and methylprednisolone has been described, but dexamethasone is much more widely studied and almost exclusively used. Dexamethasone improves the antiemetic control of 5-HT_3 antagonists by about 15% to 20%.[20] In addition to its use in the acute phase of CINV, dexamethasone is one of the cornerstone agents used to prevent delayed CINV. It is inexpensive and available in both IV and oral formulations.

The optimal dose of dexamethasone with different emetic stimuli has been studied in controlled trials.[20] For moderately emetogenic chemotherapy in the acute phase, a single 8-mg dose was as effective as larger 24-mg doses or prolonged administration. In the setting of highly emetogenic cisplatin-based chemotherapy, higher doses of 12 or 20 mg were superior to doses of 4 and 8 mg. If dexamethasone is used with aprepitant in the acute phase, the lower 12 mg prechemotherapy dose is recommended because of inhibition of steroid metabolism by aprepitant (see section on Neurokinin 1 Receptor Antagonist).[12] For prevention of delayed CINV symptoms, the most commonly used dose of dexamethasone is 8 mg twice daily on days 2 and 3 after chemotherapy without aprepitant. The dose for delayed CINV should be reduced to 8 mg daily when used with aprepitant.

Corticosteroids are sometimes underused because of the potential risk of side effects. The adverse effects of corticosteroids include insomnia, jitteriness, increased appetite, GI distress, and perineal irritation if the IV dexamethasone is infused too quickly.[18,20,27] For most patients, however, dexamethasone is well tolerated, especially because the therapy is typically short term at lower doses. Steroid-related hyperglycemia may occur, especially in patients with preexisting diabetes.[20] These patients should be advised to monitor their glucose levels more frequently and contact their practitioner if the levels remain elevated. In the nondiabetic patient, hyperglycemia is uncommon. Tapering the corticosteroid dose after the end of treatment for CINV is usually unnecessary because the duration of therapy is short. Rare patients who have steroid withdrawal-like symptoms may, however, benefit from a short taper on repeated corticosteroid courses.

Corticosteroids also have antitumor properties and are a part of the antineoplastic regimen for some malignancies, such as lymphoma, lymphoid leukemia, and myeloma, and additional dexamethasone for the antiemetic protection is not necessary. In these cases, the corticosteroid should be administered just before the rest of the chemotherapy to provide antiemetic activity. If aprepitant is part of an antiemetic regimen in a situation where the corticosteroid is given for antitumor reasons, the dose of the corticosteroid should not be reduced.[12]

NEUROKININ 1 RECEPTOR ANTAGONISTS

The potential use of NK1 receptor antagonists as antiemetics became apparent when the role of substance P in the peripheral nervous system and CNS was recognized in the emetic stimulus pathway. Aprepitant, the first NK1 receptor antagonist available, is active in both the acute and delayed phases of CINV caused by moderately and highly emetogenic chemotherapy. Aprepitant is usually given as a 3-day oral regimen, 125 mg on day 1 and 80 mg on days 2 and 3. Early trials determined that aprepitant could not replace a 5-HT_3 antagonist, but that it would be used best in conjunction with corticosteroids and a 5-HT_3 antagonist.[28]

Table 22-3

Antiemetic Agents for Chemotherapy-Induced Nausea and Vomiting

Medication (Trade Name)	Class	Indication	Dose in Adults (Doses Should be Given 30–60 Minutes Before Chemotherapy)
Aprepitant (Emend)	NK1 antagonist	Acute and delayed	PO: 125 mg on day 1, 80 mg on days 2 and 3
Dexamethasone (Decadron)	Corticosteroid	Acute (high emetogenicity)	PO/IV: 12 mg (with aprepitant) or 20 mg (without aprepitant)

		Acute (moderate emetogenicity)	PO/IV: 8–12 mg
		Acute (low emetogenicity)	PO/IV: 4–8 mg
		Delayed	PO/IV: 8 mg daily days 2–4 or days 2 and 3 or PO: 4 mg BID days 2–4
Dolasetron (Anzemet)	5-HT$_3$ antagonist	Acute	PO: 100–200 mg
Dronabinol (Marinol)	Cannabinoid	Breakthrough	PO: 2.5–10 mg PO TID to QID
Droperidol (Inapsine)	Butyrophenone	Breakthrough	IV: 0.625–1.25 mg every 4–6 hours PRN
Fosaprepitant (Emend)	NK1 antagonist	Acute	IV: 150 mg × 1 dose or 115 mg initial dose (followed by aprepitant 80 mg PO on days 2 and 3)
Granisetron (Kytril)	5-HT$_3$ antagonist	Acute	IV: 1 mg or 0.01 mg/kg PO: 2 mg TOP: 3.1 mg/24-hour patch applied 24–48 hours before chemotherapy and kept on until 24 hours after chemotherapy or up to 7 days
Haloperidol (Haldol)	Butyrophenone	Breakthrough	PO/IV/IM: 0.5–1 mg every 6 hours PRN
Metoclopramide (Reglan)	Dopamine antagonist	Breakthrough	PO/IV: 10–40 mg every 6 hours PRN
Lorazepam (Ativan)	Benzodiazepine	Breakthrough	PO/IV/IM/SL: 0.5–2 mg every 6 hours PRN
Nabilone (Cesamet)	Cannabinoid	Refractory symptoms	PO: 1–2 mg BID (max 2 mg TID)
Netupitant and palonosetron (Akynzeo)	NK1 antagonist + 5-HT$_3$ antagonist	Acute (moderate or high emetogenicity)	PO: netupitant 300 mg + palonosetron 0.5 mg
Olanzapine (Zyprexa)	Serotonin/dopamine antagonist	Acute (moderate or high emetogenicity)/delayed	PO: 10 mg on days 1–3 (moderate risk) or days 1–4 (high risk)
		Breakthrough	PO: 2.5–10 mg QHS or 2.5–5 mg BID–TID
Ondansetron (Zofran)	5-HT$_3$ antagonist	Acute (moderate or high emetogenicity) Delayed	IV: 8–12 mg or 0.15 mg/kg PO: 16–24 mg 8 mg PO BID or 8 mg IV daily
Palonosetron (Aloxi)	5-HT$_3$ antagonist	Acute/delayed	IV: 0.25 mg PO: 0.5 mg
Prochlorperazine (Compazine)	Dopamine antagonist	Breakthrough Acute	PO/IV/IM: 5–10 mg (up to 20 mg) every 4–6 hours PRN or PR: 25 mg every 12 hours PRN PO/IV: 10 mg
Promethazine (Phenergan)	Dopamine antagonist	Breakthrough	PO/IV/IM/PR: 12.5–25 mg every 4–6 hours PRN
Rolapitant (Varubi)	NK1 antagonist	Acute and delayed	PO: 180 mg on day 1

5-HT$_3$, 5-hydroxytryptamine type 3; BID, 2 times daily; IM, intramuscular; IV, intravenous; NK1, neurokinin 1;

PO, oral; PR, rectal; PRN, as needed; QHS, at bedtime; QID, 4 times daily; SL, sublingual; TID, 3 times daily.

Guideline update for MASCC and ESMO in the prevention of chemotherapy- and radiotherapy-induced nausea and vomiting: results of the Perugia consensus conference. Ann Oncol. 2010;21(Suppl 5):v232.

Aprepitant has been studied in the prevention of CINV with highly and moderately emetogenic chemotherapy.[17,28] These studies showed improved response rates when aprepitant was added to antiemetic regimens containing a 5-HT_3 antagonist plus dexamethasone.

Although CINV symptoms tend to worsen from cycle to cycle, the effects of aprepitant seem to be maintained during four cycles of chemotherapy in patients receiving moderately emetogenic chemotherapy.[29] The addition of aprepitant to the antiemetic regimen during cycle 2 (even when omitted from cycle 1) also seems to improve control of CINV symptoms.[30,31] For patients who have had inadequate response to an antiemetic regimen that did not include aprepitant, it may be useful to add it in later cycles.

The efficacy of aprepitant for the control of delayed CINV symptoms was confirmed in a trial of 489 patients comparing a standard aprepitant regimen with a regimen without aprepitant in patients receiving highly emetogenic chemotherapy.[32] The aprepitant-containing regimen offered superior control of CINV in the acute, delayed, and overall periods. The study confirmed that the aprepitant-containing regimen is superior during the delayed phase of CINV.

There is growing evidence that the prechemotherapy dose of aprepitant (or fosaprepitant) provides the majority of benefit compared with postchemotherapy doses.[17,33] The first dose of aprepitant blocks about 80% of the NK1 receptors in the CNS.[17,33] One study compared a single 150-mg IV dose of fosaprepitant with the standard three-day oral regimen (along with ondansetron and dexamethasone) in patients receiving highly emetogenic chemotherapy. No difference was found in the antiemetic efficacy between the two groups.[34]

Aprepitant is generally well tolerated with mild side effects, including fatigue, hiccups, headache, and diarrhea.[28,32] The overall adverse effects in standard aprepitant-containing regimens are not appreciably different from regimens without aprepitant. NK1 antagonists are now available as an IV prodrug, fosaprepitant and an oral fixed combination capsule of a NK1-antagonist, netupitant plus palonosetron, which offer patients different dosage forms. Netupitant and palonosetron combination therapy is recommended as an option for patients receiving highly or moderately emetogenic regimens. Trials comparing its efficacy against aprepitant have not yet been studied. Rolapitant, the newest NKI antagonist, is an oral drug with an extended half life and should not be administered at less than 2-week intervals. "Studies investigating repeat dosing of fosaprepitant, netupitant and rolapitant are not available."

Aprepitant is metabolized by the CYP3A4 enzyme system. It is a moderate inhibitor and inducer of CYP3A4 and an inducer of CYP2C9.[1,28] Consequently, several drugs potentially interact with aprepitant. The most commonly encountered interaction is with corticosteroids. Aprepitant increases the area under the curve (AUC) of dexamethasone such that the dexamethasone dose (when used as an antiemetic) should be reduced by about one-half of the usual dose when these drugs are used together.[1,17,28] The interaction is greatest when the corticosteroid is administered orally. However, when the corticosteroid is also given as part of the antitumor regimen, the corticosteroid dose should not be reduced because of concern that the antineoplastic activity might be compromised.[12] Aprepitant, fosaprepitant and netupitant inhibit the metabolism of dexamethasone. Rolapitant does not share this interaction with dexamethasone. Aprepitant may also enhance warfarin metabolism by inducing CYP2C9. International normalized ratio (INR) values in patients treated with warfarin and the standard aprepitant regimen are significantly reduced, especially on day 8 of the chemotherapy cycle.[17,28,35,36] The patient's coagulation status after aprepitant administration should be monitored, especially during the 7- to 10-day period after aprepitant. The dosage of warfarin should be adjusted if the INR is out of range. Several chemotherapy agents (paclitaxel, etoposide, ifosfamide, irinotecan, imatinib, vinca alkaloids, and others) are metabolized by the CYP3A4 enzyme system, and the metabolism of these agents may be altered by aprepitant. Aprepitant was used in clinical trials with some of these agents. Caution is warranted because the clinical relevance of this potential interaction is not known.[28,37] In comparison of NKI antagonists, there are fewer drug interactions with rolapitant when compared with aprepitant, fosaprepitant and netupitant

OLANZAPINE

Olanzapine is an atypical antipsychotic agent that antagonizes several serotonin and dopamine receptors as well as other neurotransmitter receptors.[38] Its antiemetic action was first described in patients with refractory nausea or vomiting and advanced cancer. Olanzapine has activity both in the prevention of CINV in patients at high and moderate risk and in rescue treatment for patients with refractory nausea and vomiting. Studies have demonstrated its efficacy in preventing CINV in the setting of highly and moderately emetogenic chemotherapy. Newer, controlled trials show improved response rates when added to an antiemetic regimen of a 5-HT_3 antagonist plus dexamethasone, as well as comparable activity to aprepitant.[23,35,38,39] The typical dose of olanzapine used in these trials was 10 mg PO daily on days 1 through 5.

Olanzapine is also active as a rescue agent for patients with refractory CINV. In this setting, the usual dose of olanzapine is 2.5 to 10 mg daily in one to four divided doses. The common side effects of olanzapine include sleepiness, dry mouth, and dizziness, although these were not significant in preliminary reports.[23,35,38,39] Olanzapine is an option for the prevention of CINV in patients receiving highly to moderately emetogenic regimens and a good choice for control of highly refractory CINV symptoms.

OTHER ANTIEMETICS

Medications from other drug classes have also been used as antiemetics for CINV. These include dopamine antagonists (prochlorperazine, promethazine), benzodiazepines (lorazepam), butyrophenones (droperidol, haloperidol), benzamides (metoclopramide), and cannabinoids. Many of these agents were used widely until more effective antiemetic agents became available. These agents remain useful for breakthrough symptoms or for patients who are refractory to standard therapy. The dosages and indications for these agents are shown in Table 22-3. Many of these agents have more side effects than contemporary agents do, especially sedation and extrapyramidal side effects, such as dystonia and akathisia. Lorazepam is commonly used as a rescue antiemetic. Its mechanism of action as an antiemetic is not completely understood, but it may involve disruption of the cortical impulses to the VC, as well as anxiolytic activity.

Cannabinoids have long been used for refractory nausea and vomiting. This is based on the effect of the CNS cannabinoid receptors on the CTZ, the NTS, and the VC.[40] Small trials have shown conflicting effectiveness in the prevention of CINV.[41,42] An oral cannabinoid, nabilone, was approved for the treatment of CINV in patients who do not respond adequately to other antiemetics.[40] Cannabinoids are associated with side effects, such as drowsiness, dry mouth, dysphoria, vertigo, and euphoria.[40,41] Although some patients have a clear preference for, and good response to, cannabinoids, side effects and a lack of pronounced efficacy limit their use in the general population of chemotherapy patients. These agents are usually reserved for patients who do not have adequate relief from other rescue medications.

The optimal prophylactic antiemetic regimens depend on the emetic risk of the chemotherapy regimen. Treatment guidelines have been developed by several groups, including the American Society of Clinical Oncology (ASCO; **http://jco.ascopubs.org/content/24/18/2932.full.pdf+html**)[12]; the National Comprehensive Cancer Network (NCCN; **http://www.nccn.org/professionals/physician_gls/PDF/antiemesis.pdf**; guidelines can be accessed by creating a free login)[1]; and the Multinational Association of Supportive Care in Cancer (MASCC; **http://annonc.oxfordjournals.org.floyd.lib.umn.edu/content/21/suppl_5/v232.full.p** These evidence- and consensus-based guidelines, which are similar in regard to the roles of the various antiemetics, are summarized in Table 22-4 and Figure 22-2.

Many patients may benefit from nondrug therapy for CINV symptoms, especially for anticipatory nausea and vomiting and anxiety. Techniques include guided imagery, hypnosis, relaxation techniques, systematic desensitization, and music therapy.[43] Acupuncture and acupressure techniques have been investigated for use in CINV, and some patients benefit from their use. The use of acupressure devices that stimulate the P6 point on the wrist have been proposed; however, in a controlled trial in patients with breast cancer, it was not found to be helpful.[44] If patients are troubled by CINV symptoms, it is recommended that they refrain from heavy meals for 8 to 12 hours prior to chemotherapy. They should also avoid heavy, greasy foods and food with strong aromas. Chewing gum can mask the metallic taste that some patients perceive. Dry, salty foods can also help settle the stomach.

Table 22-4

Recommended Antiemetic Regimens for Chemotherapy-Induced Nausea and Vomiting by Emetogenicity of Chemotherapy Regimen

Emetogenicity Potential	Acute-Phase CINV (Doses Should be Given 30–60 Minutes Before Chemotherapy)	Delayed-Phase CINV	Breakthrough CINV
High-risk IV chemotherapy regimens	**Aprepitant-containing regimen**		Two agents for PRN use
	Day 1: single dose 5-HT$_3$ antagonist + dexamethasone 12 mg PO/IV + aprepitant 125 mg PO once/fosaprepitant 150 mg IV once	Dexamethasone 8 mg PO/IV on days 2–4 + aprepitant 80 mg days 2–3 (not needed if fosaprepitant 150-mg dose used)	
	Netupitant-containing regimen		
	Day 1: netupitant 300 mg/palonosetron 0.5 mg PO once + dexamethasone 12 mg PO/IV once	Dexamethasone 8 mg PO/IV on days 2–4	
	Olanzapine-containing regimen		
	Day 1: Olanzapine 10 mg PO once + palonosetron 0.25 mg IV once + dexamethasone 20 mg IV once	Olanzapine 10 mg PO daily on days 2–4	
High risk	**Rolapitant-containing regimen** Day 1: Rolapitant 180 mg PO once + palonosetron 0.25 mg IV once + dexamethasone 12 mg PO/IV once	Dexamethasone 8 mg PO/IV twice daily on days 2–4	
Moderate risk	**Rolapitant-containing regimen** Day 1: Rolapitant 180 mg PO once + palonosetron 0.25 mg IV once + dexamethasone 12 mg PO/IV once	Dexamethasone 8 mg PO/IV daily on days 2–3	
Moderate-risk IV	**Aprepitant-containing regimen**		Two agents for

chemotherapy regimens	Day 1: single dose 5-HT$_3$ antagonist + dexamethasone ± aprepitant/fosaprepitant	Days 2–3: 5-HT$_3$ antagonist or dexamethasone or aprepitant	PRN use
	Netupitant-containing regimen		
	Day 1: netupitant 300 mg/palonosetron 0.5 mg PO once + dexamethasone 12 mg PO/IV once	Dexamethasone 8 mg PO/IV on days 2–3	
	Olanzapine-containing regimen		
	Day 1: Olanzapine 10 mg PO once + palonosetron 0.25 mg IV once + dexamethasone 20 mg IV once	Olanzapine 10 mg PO daily on days 2–3	
Low-risk IV chemotherapy regimens	Single dose dexamethasone or metoclopramide or prochlorperazine or 5HT$_3$ antagonist	None	Either none or one agent for PRN use
Minimal-risk IV chemotherapy regimens	None	None	Usually none
High- to moderate-risk PO chemotherapy regimens	5-HT$_3$ antagonist	None	One agent for PRN use
Low-risk PO chemotherapy regimens	None	None	One agent for PRN use

5-HT$_3$, 5-hydroxytryptamine type 3; CINV, chemotherapy-induced nausea and vomiting; IV, intravenous; PO, oral; PRN, as needed.

Patient receiving first cycle of chemotherapy
Consider patient risk factors
Determine the highest emetogenicity of the chemotherapy given on each day
Highly emetogenic chemotherapy
Moderately emetogenic chemotherapy with risk of delayed CINV
Moderately emetogenic chemotherapy without a high risk of delayed CINV
Low emetogenicity chemotherapy
Minimal emetogenicity chemotherapy
Acute phase: single-dose 5-HT3-RA + dexamethasone + fosaprepitant/aprepitant
Acute phase: single-dose 5-HT3-RA + dexamethasone + fosaprepitant/aprepitant
Acute phase: single-dose 5-HT3-RA + dexamethasone
Acute phase: prochlorperazine or metoclopramide or dexamethasone or
Acute phase: none
Delayed phase: dexamethasone D2-4 + aprepitant D2-3 (not if fosaprepitant 150 mg used)
Delayed phase: dexamethasone D2-3 + aprepitant D2-3
Delayed phase: none
Delayed phase: none
Delayed phase: none
Provide two PRN medications
Provide two PRN medications
Provide one PRN medication
Provide one PRN medication
Possibly one PRN medication
Monitor patient for efficacy and toxicity
Adverse effects from antiemetics
More than minimal breakthrough symptoms
Minimal or no breakthrough symptoms; no toxicity
Reduce dose for drowsiness/confusion, offer pain medication for headaches, offer hypnotic agents for insomnia, monitor glucose and give insulin for hyperglycemia
Schedule PRN medications, add other PRN medications, consider need for IV hydration or electrolyte supplementation
No change in therapy

Figure 22-2 Algorithm for antiemetic selection of an initial chemotherapy cycle. CINV, chemotherapy-induced nausea and vomiting; PRN, as needed; 5-HT$_3$-RA, 5-hydroxytryptamine type 3 receptor antagonist.

Clinical Presentation and Risk Factors

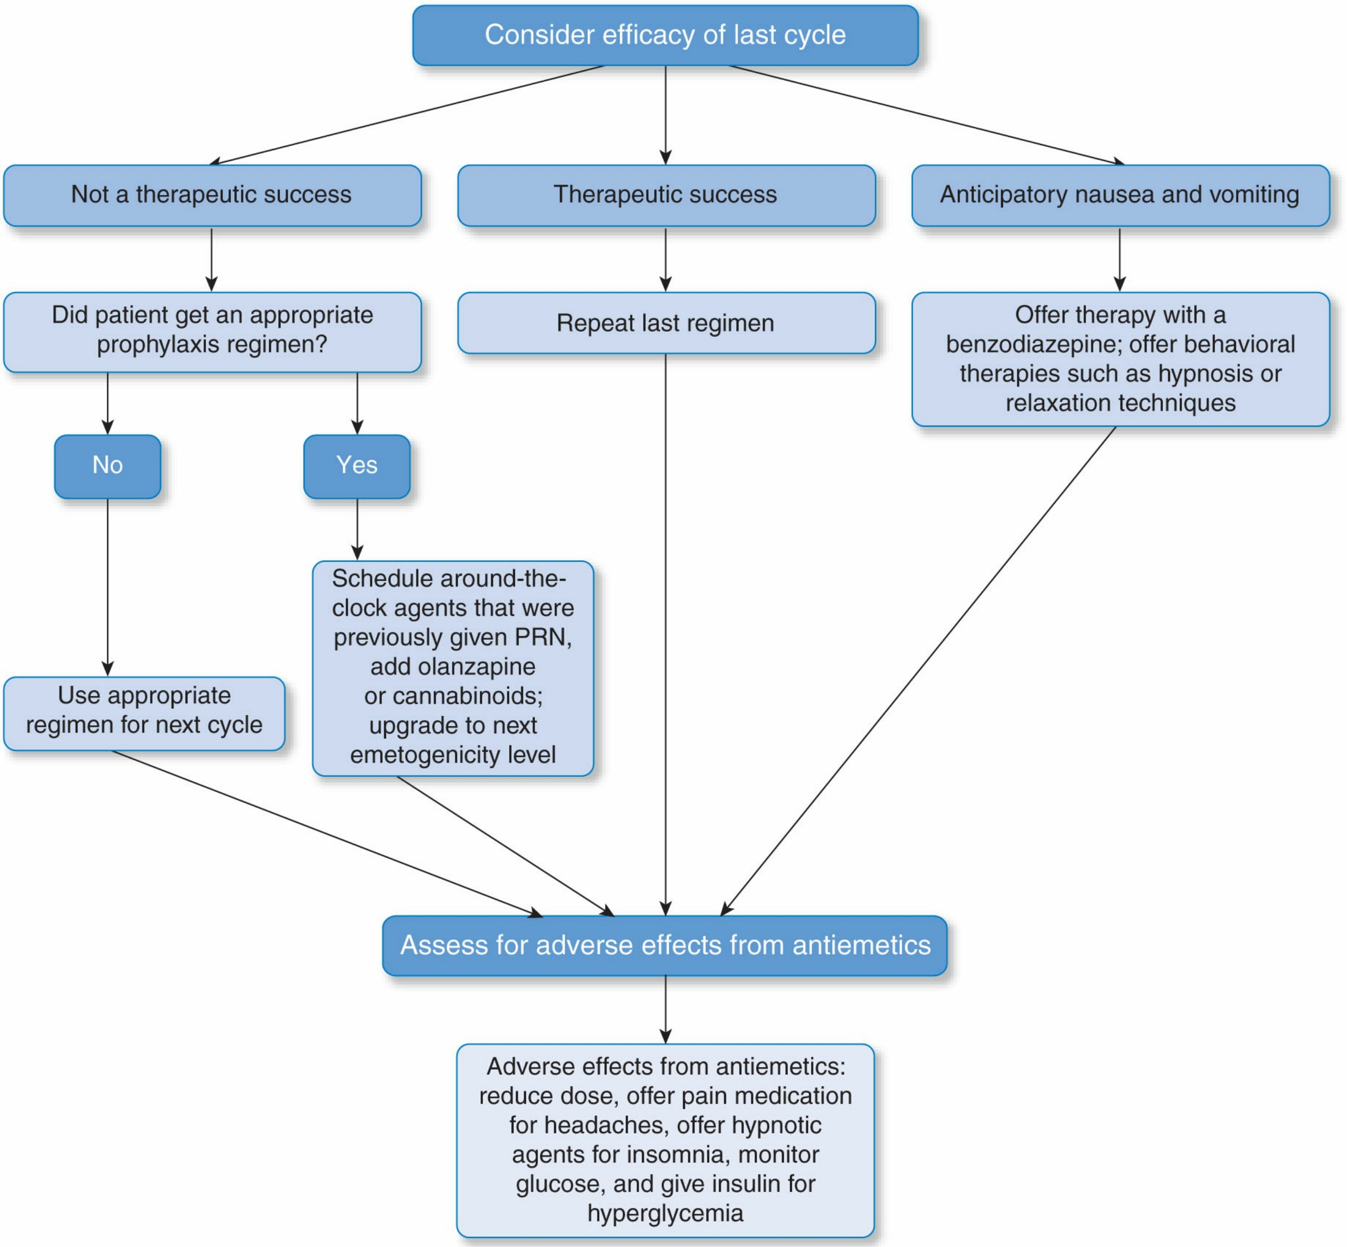
CASE 22-2

QUESTION 1: M.C., a 54-year-old woman with breast cancer, is in the clinic today to receive her first cycle of chemotherapy. Her chemotherapy will consist of docetaxel 75 mg/m^2 IV, carboplatin dosed to achieve an AUC of 6 mg/mL × min. This will be repeated every 21 days. In addition, she will receive trastuzumab 4 mg/kg IV for one dose, then 2 mg/kg/week for 17 weeks. M.C. does not drink alcohol or smoke. Her only other medical condition is adult-onset diabetes, which is controlled with metformin and diet. She has had four children, now all grown, and had substantial morning sickness with each of her pregnancies. M.C.'s neighbor told her that all chemotherapy causes severe nausea and vomiting. How likely is M.C. to experience nausea and vomiting? What are her risk factors?

M.C. is at moderate risk for acute CINV. Her personal risk factors include female sex, history of morning sickness with pregnancy, and being a nondrinker. The docetaxel has a low risk of acute CINV, the carboplatin has a moderate risk of acute CINV with a high risk of delayed CINV, and the trastuzumab has a minimal risk of acute CINV. A moderate-risk prophylactic regimen should be recommended for M.C.

CASE 22-2, QUESTION 2: What antiemetics are available for M.C.?

For moderate-risk prophylaxis, an aprepitant-, netupitant-, rolapitant-, or olanzapine-containing regimen is recommended. For a single-day chemotherapy regimen, the aprepitant-containing regimen includes a single dose of 5-HT_3 antagonist plus dexamethasone 8 to 12 mg oral or IV plus oral aprepitant 125 mg on day 1, then oral dexamethasone 8 mg on days 2 through 4, and oral aprepitant 80 mg on days 2 and 3. The olanzapine-containing regimen includes olanzapine 10 mg oral on days 1 to 3, dexamethasone 20 mg IV once on day 1, and palonosetron 0.25 mg IV once on day 1. The netupitant-containing regimen includes netupitant 300 mg plus palonosetron 0.5 mg oral on day 1, then oral dexamethasone 12 mg on day 1 and 8 mg oral or IV daily on days 2 to 3. The rolapitant-containing regimen includes rolapitant 180 mg PO, a 5HT3 antagonist & dexamethasone 12 mg oral on day 1, then oral dexamethasone 8 mg PO on day 2 and 3.



Consider efficacy of last cycle
Not a therapeutic success
Therapeutic success
Anticipatory nausea and vomiting
Did patient get an appropriate prophylaxis regimen?
Repeat last regimen
Offer therapy with a benzodiazepine; offer behavioral therapies such as hypnosis or relaxation techniques
No
Yes
Schedule around-the-clock agents that were previously given PRN, add olanzapine or cannabinoids; upgrade to next emetogenicity level
Use appropriate regimen for next cycle
Assess for adverse effects from antiemetics
Adverse effects from antiemetics: reduce dose, offer pain medication for headaches, offer hypnotic agents for insomnia, monitor glucose, and give insulin for hyperglycemia

Figure 22-3 Algorithm for selection of antiemetic regimens for subsequent chemotherapy cycles. PRN, as needed.

CASE 22-2, QUESTION 3: M.C. is at moderate risk for acute nausea and vomiting and at high risk for delayed CINV symptoms, as a result of her chemotherapy regimen of docetaxel, carboplatin, and trastuzumab. What would be the most appropriate antiemetic regimen for M.C.?

For M.C., the best regimen would be an aprepitant, netupitant, or rolapitant-containing regimen. The olanzapine-containing regimen is also an option but used cautiously in patients with diabetes mellitus. She should be offered medications for breakthrough CINV symptoms, such as prochlorperazine and lorazepam. She should be warned of the potential adverse effects of dexamethasone or olanzapine, especially hyperglycemia, and counseled to check her blood sugar levels more frequently and contact her physician if they remain elevated. M.C. should be advised to maintain a record of her symptoms and contact her physician if the breakthrough medications are not working or if she cannot keep fluids down.

If M.C. had been prescribed a multiday chemotherapy regimen, prophylaxis with a

5-HT_3 antagonist and dexamethasone should be offered for each day that moderately or highly emetogenic chemotherapy is administered.[1,12,13,45] If multiday chemotherapy regimens have a high risk of delayed symptoms, then therapy (e.g., dexamethasone plus prochlorperazine or metoclopramide, if aprepitant was already administered) for the delayed symptoms should be continued for at least 2 to 3 days after the last chemotherapy administration.

Modern antiemetic regimens achieve complete emetic control in about 70% to 90% of patients, but the response rate is lower for delayed CINV symptoms. If CINV symptoms are not adequately controlled, alterations in the prophylactic antiemetic regimen should be made for the next cycle (Fig. 22-3). Suggestions include upgrading to the next higher emetogenicity level recommendation, adding aprepitant if not already given, and scheduling antiemetic agents from other pharmacologic classes.

RADIATION-INDUCED NAUSEA AND VOMITING

Clinical Presentation and Risk Factors

CASE 22-3

QUESTION 1: E.G. is a 54-year-old man with newly diagnosed head and neck cancer who will receive radiation therapy concurrently with chemotherapy containing cisplatin and fluorouracil. His daily (Monday through Friday) radiation treatments will last for 6 weeks. He has a heavy smoking history (35 pack-years) and "quit" last week, although it is not going well. After E.G.'s nausea and vomiting from the chemotherapy subsides, is he at risk for experiencing radiation-induced nausea and vomiting (RINV)? What antiemetic prophylaxis is appropriate?

Radiation therapy can cause nausea and vomiting through the same basic pathways that chemotherapy does. RINV affects 40% to 80% of patients receiving radiation therapy. The risk of RINV depends on several factors, namely, the size and area to be irradiated, larger fractional doses of radiation, and whether the patient has had previous chemotherapy.[1,46,47] Patients with radiation areas larger than 400 cm^2 are more likely to have significant RINV symptoms. The radiation therapy oncologist will determine the size of the radiation field and fractional doses of radiation to maximize the efficacy of the radiation therapy. The high dose used in total body irradiation (associated with hematopoietic stem cell transplantation) causes RINV in more than 90% of patients. Patients receiving radiation to the upper abdominal area experience nausea and vomiting about 50% to 80% of the time. Radiation to other areas of the body is less likely to cause nausea and vomiting.

Overview of Treatment

Just as with CINV, symptoms caused by radiation can be prevented with 5-HT_3 antagonists, corticosteroids, or both. Evidence- and consensus-based recommendations have been published by several multidisciplinary groups and are shown in Table 22-5. High-risk RINV is best treated with a combination of a 5-HT_3 antagonist and a corticosteroid.[1,46–50] Patients receiving concomitant chemotherapy and radiation should receive antiemetics appropriate for the chemotherapy regimen.[1] Patients receiving radiotherapy in the moderate RINV risk group can receive either prophylaxis or rescue therapy with a 5-HT_3 antagonist.

E.G. is at low risk for experiencing RINV because his radiation site will be in the head and neck region, his radiation site is not likely to be larger than 400 cm^2, and he will likely receive a smaller fractional dose, although he will be receiving concurrent chemotherapy. Because E.G. is at low risk for having RINV symptoms, he does not need prophylaxis with a 5-HT_3 antagonist. If he experiences symptoms, rescue therapy with a dopamine antagonist or a serotonin antagonist should be offered.

POSTOPERATIVE NAUSEA AND VOMITING

Clinical Presentation and Risk Factors

CASE 22-4

QUESTION 1: E.W. is a 48-year-old woman who is scheduled for a laparoscopic cholecystectomy. The scheduled duration of her surgery is less than an hour. Her medical history includes hypertension. She does not have a history of motion sickness, and she is a nonsmoker. E.W. has never had surgery before. Her sister-in-law had severe nausea and vomiting after an outpatient surgical procedure last year, and E.W. is worried that she too may have it. What is E.W.'s risk of having postoperative nausea and vomiting (PONV)? What can be done to reduce her risk, and how can symptoms be treated if they occur?

Table 22-5

Prophylaxis for Radiation-Induced Nausea and Vomiting for Adults

Emetic Risk	Radiation Area	Recommendation
High risk	Total body irradiation	Prophylaxis with a 5-HT_3 antagonist (e.g., ondansetron 8 mg PO BID–TID or granisetron 2 mg PO daily) ± dexamethasone 4 mg PO daily
Moderate risk	Upper abdomen	Prophylaxis with a 5-HT_3 antagonist (e.g., ondansetron 8 mg PO BID or granisetron 2 mg PO daily) ± dexamethasone 4 mg PO daily
Low risk	Lower thorax, pelvis,	Prophylaxis or rescue with a 5-HT_3 antagonist

	cranium, craniospinal region, head/neck	
Minimal risk	Extremities, breast	Rescue with a dopamine antagonist or a 5-HT_3 antagonist

5-HT3, 5-hydroxytryptamine type 3; BID, twice daily; PO, oral; TID, 3 times daily.

J Natl Compr Canc Netw. 2007;5:60.

PONV is a common complication of surgery, affecting 25% to 30% of all patients but up to 80% of patients in high-risk groups.[51] In surgical patients, PONV can lead to hospitalizations, stress on the surgical closure, hematomas, and aspiration pneumonitis. Patient-related, surgical, and anesthetic factors can increase the risk of PONV.[51–55] Patient risk factors include female sex, history of motion sickness, nonsmoking status, obesity, and a history of PONV. Some surgical risk factors for PONV include long duration of surgery and type of surgical procedure (e.g., laparoscopy, ear–nose–throat procedures, gynecologic surgeries, and strabismus repair). Anesthetic risk factors include the use of volatile anesthetics or nitrous oxide (as opposed to IV propofol) and the use of intraoperative or postoperative opioids. Children are twice as likely to have PONV as adults.[52,56] The risk increases with the child's age but declines after puberty.

Certain anesthesia practices may reduce the risk of PONV. These include use of regional anesthesia (instead of general anesthesia); use of total IV anesthesia with propofol; use of intraoperative oxygen; adequate hydration; and avoidance of nitrous oxide, volatile anesthesia therapy, and intraoperative or postoperative opiates.[51–53,55–57]

Table 22-6

Medications for Prevention and Treatment of Postoperative Nausea and Vomiting in Adults

		Treatment or Rescue

Medication	Prophylactic Dose	Dose
Aprepitant	40 mg PO within 3 hours before induction of anesthesia	None
Dexamethasone	4–10 mg at the start of induction of anesthesia	2–4 mg IV
Dolasetron	12.5 mg IV at end of surgery	12.5 mg IV
Droperidol	0.625–1.25 mg IV at end of surgery	0.625–1.25 mg IV or IM every 4–6 hours
Metoclopramide	10–20 mg IV at end of surgery	10–20 mg IV or IM every 6 hours
Granisetron	0.35–1 mg IV at end of surgery	0.1 mg
Ondansetron	4–8 mg IV at end of surgery	1 mg IV every 8 hours
Palonosetron	0.075 mg IV immediately prior to induction of anesthesia	None
Prochlorperazine	5–10 mg IV at end of surgery	5–10 mg IV or IM every 4–6 hours
Promethazine	12.5–25 mg IV at induction or end of surgery	12.5–25 mg IV or IM every 4–6 hours
Scopolamine	1.5 mg TOP evening before surgery or at least 4 hours before end of surgery	

IM, intramuscular; IV, intravenous; PO, oral; TOP, topical patch.

Several risk factor models have been studied to correlate these factors into recommendations for prevention and therapy.[51,53] One model is both simple and practical and uses the following risk factors: female sex, history of PONV or motion sickness, nonsmoking status, surgery longer than 60 minutes in duration, and the use of intraoperative opioids. If the patient has zero or one risk factor, the risk of PONV is about 10% to 20%, and no prophylaxis is necessary unless there is a medical risk for emesis. If the patient has two or more risk factors, the incidence increases to 40% to 80%, and prophylaxis with one or two medications is warranted. E.W. has at least two risk factors (female, nonsmoker) and may have more if her surgery lasts longer than expected or if she receives intraoperative or postoperative opioids. She has a moderate to high risk of PONV.

Overview of Treatment

An optimal prophylactic regimen for PONV matches medication choice with the patient's risk level.[51–53,55,56,58] Patients with zero or one risk factor typically will not need prophylaxis. Patients with moderate risk (two to three risk factors) should receive one to two antiemetics. Appropriate choices for monotherapy include droperidol, a 5-HT$_3$ antagonist, or dexamethasone. Patients at the highest risk for PONV (at least four risk factors) should be given prophylaxis with a combination of two to three antiemetics. Dual-therapy choices include a 5-HT$_3$ antagonist plus either droperidol or dexamethasone. Triple therapy would combine a 5-HT$_3$ antagonist plus dexamethasone plus droperidol. Because E.W. has a moderate to high risk for PONV, a combination of a 5-HT$_3$ antagonist (such as ondansetron 4–8 mg at the end of surgery) and dexamethasone (4–8 mg at the start of anesthesia induction) would be a good choice for prophylactic therapy.

The most effective and commonly used medications for the prevention of PONV include 5-HT$_3$ antagonists, dexamethasone, droperidol, and combinations of these agents. No appreciable difference is found in efficacy or adverse effects between the 5-HT$_3$ antagonists; therefore, the costs of the different agents should be taken into consideration when selecting therapy.[51,59] Droperidol has long been used for PONV, but concerns have been raised about the rare occurrence of QT prolongation and torsades de pointes.[58,60] Most clinicians believe droperidol to be safe, especially when doses are not excessive (up to 1.25 to 2.5 mg/dose for adults).[52,60,61] The mechanism by which dexamethasone protects against PONV is unclear, but its efficacy has been shown in many trials.[52,56,58] Combinations of medications with different mechanisms of action are more effective than monotherapy. Aprepitant has been studied in the prevention of PONV.[28,51,52] Studies have shown similar activity of aprepitant compared with ondansetron.[28,51,52] Aprepitant, however, is significantly more expensive than generic ondansetron or dexamethasone, which is a consideration. The use of aprepitant is also limited by the potential for drug interactions.[55] Dexamethasone and 5-HT$_3$ antagonist combinations have been well studied and are highly effective.[51,52,56,58,61] Transdermal scopolamine is also effective but can have side effects.[51] Dosages for the prophylaxis and treatment of PONV are shown in Table 22-6. The 5-HT$_3$ antagonists and droperidol seem to be more effective when given at the end of surgery. Corticosteroids are best given before the induction of anesthesia.[52,60]

Several methods for nonpharmacologic techniques for the prevention of PONV have been studied and have been shown to be effective, at least in some patient populations. These include acupuncture, transcutaneous nerve stimulation, acupressure at the P6 wrist point, hypnosis, and aromatherapy with isopropyl alcohol. Ginger remedies were not found to be more effective than placebo for PONV.[52]

Even with appropriate prophylaxis for PONV, some patients will experience breakthrough symptoms and require rescue therapy.[51] Patients who have not received prophylaxis with a 5-HT_3 antagonist can be offered a low dose of a 5-HT_3 antagonist for rescue. For rescue, only about one-quarter of the prophylaxis dose is needed.[52] For all patients who have breakthrough symptoms, it is important to choose an antiemetic from a different pharmacologic class than

---

the agents used for prophylaxis.[51,53,58] Droperidol, promethazine, metoclopramide, and prochlorperazine are commonly used as rescue medications. If E.W. had breakthrough nausea, droperidol (0.625–1.25 mg IV or intramuscular every 4–6 hours as needed) would be a good choice for rescue therapy.

Upper Gastrointestinal Disorders

Elaine J. Law and Jeffrey J. Fong

CORE PRINCIPLES	CHAPTER CASES
PEPTIC ULCER DISEASE	
① Chronic peptic ulcer disease (PUD) is causally linked to Helicobacter pylori (H. pylori) infection or the use of nonsteroidal anti-inflammatory drugs (NSAIDs) and is usually characterized by epigastric pain or discomfort, sometimes accompanied by heartburn, bloating, and belching.	**Case 23-1 (Questions 1, 2), Case 23-2 (Question 1), Case 23-4 (Question 3)**
② Treatment for PUD is aimed at relieving ulcer symptoms, healing the ulcer, eradicating H. pylori (if positive), preventing ulcer recurrence, and reducing ulcer-related complications; eradication is recommended for all patients with an H. pylori–positive active ulcer or a history of a previous ulcer or ulcer-related complication; proton-pump inhibitors (PPIs) are the drugs of choice for healing and reducing the risk of an NSAID ulcer; patients with a peptic ulcer should stop or reduce cigarette smoking and NSAID use, reduce psychologic stress, and avoid foods and beverages that trigger symptoms.	**Case 23-1 (Questions 3–10), Case 23-2 (Questions 2–10)**
③ Treatment for an H. pylori ulcer should be initiated with a PPI-based three-drug eradication regimen; the regimen should be effective, well-tolerated, easy to comply with, cost-effective, and should take into consideration antibiotic resistance; if a second course of therapy is necessary, it should contain different antibiotics.	**Case 23-1 (Questions 3, 4, 6–10)**
④ PPIs are the preferred agents for healing an H. pylori–negative NSAID ulcer because they accelerate ulcer healing and provide more effective symptom relief; the duration of treatment should be extended if the NSAID is continued; if the patient is H. pylori positive, a PPI-based three-drug regimen should be used.	**Case 23-2 (Questions 2, 3, 10)**
⑤ Prophylactic risk-reduction therapy with a PPI or misoprostol or switching to an NSAID with greater cyclooxygenase-2 (COX-2) selectivity is recommended for patients at risk of exhibiting an ulcer or ulcer-related complication; when selecting a PPI, its gastrointestinal benefits must be weighed against the cardiovascular risks associated with COX-2 inhibitors and concomitant antiplatelet therapy.	**Case 23-2 (Questions 4–7), Case 23-5 (Question 2)**
⑥ Patients receiving an H. pylori eradication regimen, those undergoing treatment for an active NSAID ulcer, and individuals receiving	**Case 23-1 (Question 5), Case 23-2 (Questions 8, 9)**

prophylactic risk-reduction therapy require patient education regarding ulcer risk, potential ulcer complications, and drug therapy.	

GASTROESOPHAGEAL REFLUX DISEASE

① The classic symptoms associated with gastroesophageal reflux disease (GERD) are usually very specific and include heartburn and acid regurgitation; however, not all patients will present with these typical symptoms and may present with more serious “alarm symptoms” or extra esophageal manifestations, warranting referral for further evaluation.	**Case 23-3 (Question 1)**
② Appropriate management of the patient with GERD is focused on the relief of symptoms, promotion of healing of the esophageal mucosa, and prevention of relapse or the development of complicated disease. This is accomplished with lifestyle modification and pharmacotherapy directed at reducing esophageal mucosal exposure to gastric acid.	**Case 23-3 (Questions 2–4)**

③ Diagnostic testing strategies for patients with more severe GERD include empiric acid suppression test, upper endoscopy and biopsy, 24-hour continuous pH monitoring, radiologic testing, and esophageal manometry.	**Case 23-4 (Question 1)**
④ Mild to moderate GERD can be managed acceptably with antacids, sucralfate, and H_2RAs; however, for more severe, frequent, or complicated GERD, the drugs of choice are PPIs, which have demonstrated superiority over these other agents in terms of symptom relief and esophageal healing.	**Case 23-4 (Question 2)**
⑤ GERD can be associated with numerous manifestations that occur outside the esophagus, including noncardiac chest pain, asthma, hoarseness, laryngitis, and chronic cough.	**Case 23-5 (Question 1)**

UPPER GASTROINTESTINAL BLEEDING

① Stress-related mucosal bleeding (SRMB) is a serious complication that can occur in critically ill patients under severe physiologic stress. Appropriate prophylactic management includes identification of risk factors for SRMB, such as mechanical ventilation and coagulopathy, and then implementation of an appropriate pharmacotherapy strategy (e.g., PPIs, H_2RAs) aimed at reducing the risk of exhibiting SRMB.	**Case 23-6 (Questions 1–4)**

UPPER GASTROINTESTINAL DISORDERS

Upper gastrointestinal (GI) disorders include a wide spectrum of maladies that range in importance from simple discomfort to life-threatening illness and include dyspepsia, peptic ulcer disease (PUD), gastroesophageal reflux disease (GERD), and upper GI bleeding. The majority of upper GI disorders are acid-related diseases in which gastric acid plays an important role in their development, progression, and treatment. In the United States, GI disorders add up to $142 billion in direct and indirect costs each year, with more than $10 billion of this amount spent on proton-pump inhibitors (PPIs), a primary pharmacotherapeutic option used to reduce gastric acid secretion.[1] These diseases place a substantial burden on both patients and the health-care system. Data from 2009 indicated that abdominal pain was the most common GI symptom reported by patients, leading to 15.9 million clinic visits, with GERD being the most frequent outpatient diagnosis, accounting for almost 9 million clinic visits.[1] Between 250,000 and 300,000 patients are hospitalized each year for upper GI bleeding, resulting in 15,000 to 30,000 deaths. Despite numerous advances in diagnostic techniques and management strategies, mortality rates of approximately 10% to 15% are reported with more than $2.5 billion spent each year to manage these patients.[2–4]

PHYSIOLOGY OF THE UPPER GASTROINTESTINAL TRACT

The upper GI tract consists of the mouth, esophagus, stomach, and duodenum (Fig. 23-1). Ingested food or liquids pass from the mouth through the esophagus and into the stomach. As these substances enter into the esophagus, the lower esophageal sphincter (LES), an area of smooth muscle near the distal end of the esophagus, relaxes to allow their entry into the stomach. The LES usually remains contracted to prevent the reflux of gastric contents into the esophagus. However, peristaltic contractions of the esophageal muscles allow the LES to remain open until all food has entered the stomach.[5] Although the LES is the primary barrier for the prevention of gastric refluxate entering the esophagus, healthy individuals reflux throughout the day and night without clinical consequences.[6]

The stomach consists of three distinct anatomic regions, each responsible for a variety of specialized functional processes (Fig. 23-1). The cardia (~5% of stomach surface area), which is the uppermost portion of the stomach, is at the junction between the esophagus and stomach and is responsible for the mucus secretion that protects against the stomach’s acidic environment. The body, which makes up the majority of the surface area (80% to 90%) of the stomach, contains the parietal cells, which are responsible for gastric acid and intrinsic factor (required for vitamin B_{12} absorption) secretion. The body also contains the peptic (chief) cells, which secrete pepsinogen. Pepsinogen, under acidic conditions in the stomach, is converted to pepsin (a proteolytic enzyme), which is responsible for breaking down protein. The antrum makes up the final 10% to 20% of the stomach. It contains the G cells. The final portion of the upper GI tract is the duodenum, which begins just after the pylorus and extends to the ligament of Treitz. At this point, the jejunum begins the first portion of the lower GI tract.

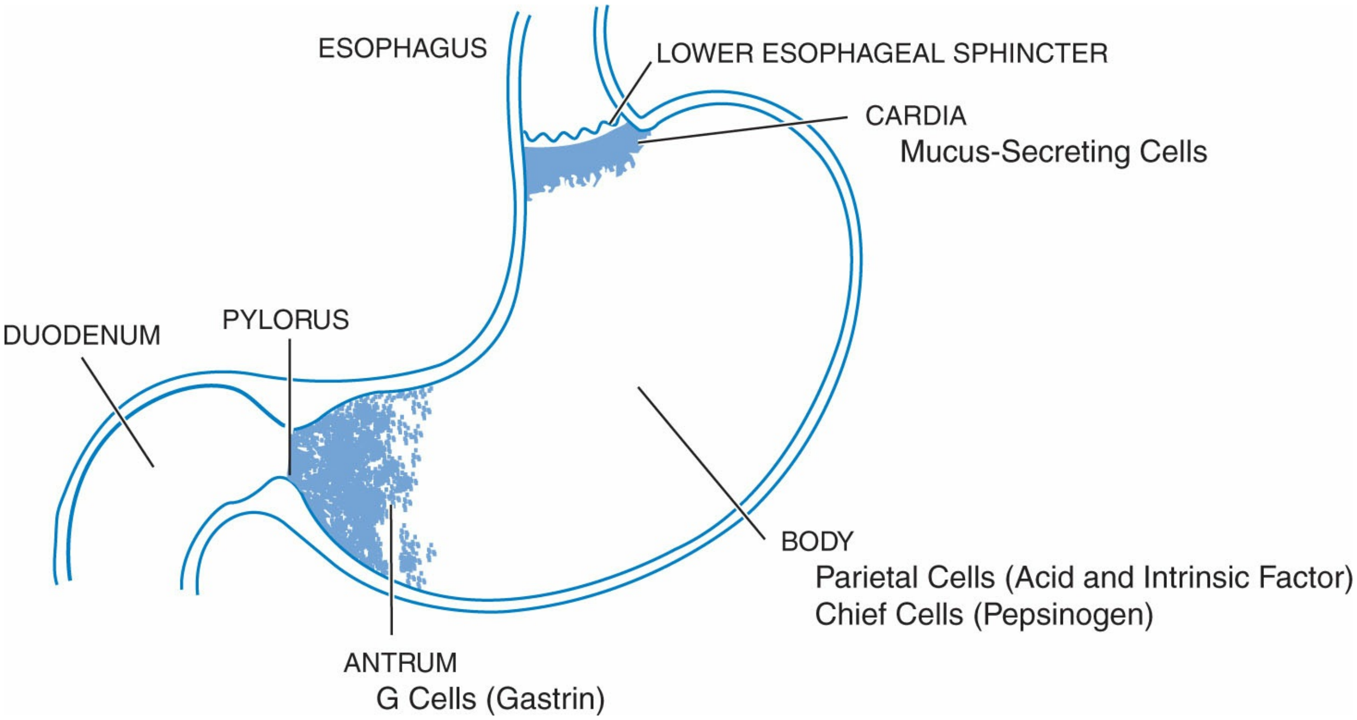

Figure 23-1 Gastrointestinal anatomic regions.

The parietal cell is responsible for secreting gastric acid (Fig. 23-2). Three stimuli (neurologic, physical, and hormonal) trigger the parietal cell to secrete acid. Neurologic impulses, from the central nervous system (CNS) and initiated by the sight, smell, and taste of food, travel along cholinergic pathways to stimulate the release of acetylcholine, which arrives via nerve endings and activates the muscarinic receptor on the parietal cell.[7] Ingested food causes gastric distension, which triggers the release of acetylcholine and also stimulates G cells within the antrum to produce gastrin. Elevated intragastric pH also stimulates the production of gastrin. Gastrin works via a feedback mechanism that, although produced in response to elevated pH, can be inhibited by low gastric pH. The stomach is protected from overproduction of gastric acid by the release of somatostatin from antral D cells, which signal the G cell to stop the production of gastrin.[7,8] Gastrin enters the blood and arrives at the parietal cell, where it binds to the gastrin receptor. Acetylcholine and gastrin promote the release of histamine from the mast cell or enterochromaffin-like (ECL) cells, which then bind to the histamine H_2 receptor on the parietal cell. Histamine release is associated with both postprandial and nocturnal acid secretion. The gastrin, histamine H_2, and muscarinic receptors are located on the basolateral membrane of the parietal cell and binding of any of these receptors leads to a cascade of events stimulating gastric acid secretion (Fig. 23-2). Calcium influxes into the parietal cell, leading to increased intracellular levels of calcium. Levels of cyclic adenosine monophosphate also increase and activate intracellular protein phosphokinases. This, in turn, activates the hydrogen–potassium adenosine triphosphatase (H^+/K^+-ATPase) or proton pump to move into position in the secretory canaliculus located in the apical membrane of the parietal cell. The proton pump is an ion transport pathway that transports hydrogen ions out of the cytoplasm and into the secretory canaliculus, where they are exchanged for potassium ions that enter the parietal cell via the opposite ion channel. In the secretory canaliculus, hydrogen ions combine with chloride from the blood to form hydrochloric acid, which is then released into the gastric acid lumen.[7] The proton pump is the final common pathway for gastric acid secretion.[7]

PHARMACOTHERAPY OF DRUGS USED TO

TREAT ACID-RELATED DISORDERS

The following section briefly reviews the pharmacotherapy of drugs used to treat acid-related disorders (Table 23-1). Their therapeutic use is discussed under each specific GI disorder.

Antacids and Alginic Acid

Antacids are widely used to relieve mild and infrequent symptoms associated with acid-related diseases. They act by neutralizing gastric acid and, thus, increasing intragastric pH.[9] The elevation of intragastric pH is dose-dependent and usually requires a substantial dose to raise the intragastric pH above 4 or 5.[9,10] Antacids are very quick acting and modestly elevate intragastric pH within minutes, but their duration of action is short (about 30 minutes on an empty stomach). The duration of action can be extended to 3 hours when given with or within 1 hour after a meal.[9] Antacids are available as individual salts or as combination of salts of magnesium, aluminum, calcium, or sodium. Aluminum salts may enhance mucosal protection by increasing mucosal prostaglandins, enhancing microvascular blood flow, stimulating mucus and bicarbonate secretion, and also by inhibiting the action of pepsin. These findings suggest that in addition to their acid-neutralizing capacity, antacids have other mechanisms by which they act. This helps to explain their many pharmacotherapeutic benefits.[9] A review of specific antacid products and their acid-neutralizing capacity is discussed elsewhere.[9] Antacids can also be combined with alginic acid. Alginic acid, however, is not an acid-neutralizing agent. It acts by forming a viscous solution that floats on top of the gastric contents and theoretically protects the esophageal mucosa from the potent acid refluxate.[11]

Antacids are generally well tolerated. The magnesium-containing antacids may cause a dose-related osmotic diarrhea but combining it with aluminum salts (which can cause constipation when used alone) can offset this side effect. When higher doses of combination of magnesium/aluminum antacids are used, the predominating side effect is diarrhea.[9,12] Small amounts of aluminum and magnesium are absorbed systemically and have the potential to accumulate in patients with renal insufficiency and lead to toxicity. Thus, magnesium-containing antacids should be avoided in patients with a creatinine clearance less than 30 mL/minute, and chronic use of aluminum-containing antacids in patients with renal failure should be avoided.[9,12] Hypercalcemia has been described in patients taking prolonged, large doses of calcium carbonate (>20 g/day in patients with normal renal function and >4 g/day in patients with renal failure).[9] This issue is especially important when considering that many well-known over-the-counter (OTC) antacid products currently contains calcium.[12] High-dose regimens of calcium (4–8 g/day) in combination with alkalinizing agents (sodium bicarbonate) can produce the milk-alkali syndrome (i.e., hypercalcemic nephropathy with alkalosis).[9,12] Aluminum-containing antacids (with the exception of aluminum phosphate) binds to dietary phosphate within the GI tract to form insoluble salts that are excreted in feces. High dose or frequent administration may lead to hypophosphatemia.[12] Sodium bicarbonate should not be used for long periods of time (especially in the renally impaired patient) because systemic alkalosis can result from the accumulation of bicarbonate. Additionally, the high sodium content (274 mg sodium/g sodium bicarbonate) has been associated with sodium retention and may pose a problem in patients with hypertension, ascites, severe renal dysfunction, or heart failure.[9,12]

Sucralfate	1 g QID	Not indicated	Not indicated	Not indicated	Not indicated	Not indicated	Not ind
	2 g BID						
Misoprostol	Not indicated	Not indicated	200 mcg TID–QID	Not indicated	Not indicated	Not indicated	Not ind

[a] Although FDA labeled for this indication, H$_2$RAs are not recommended even in higher dosages because they are not as effective as the PPIs.
[b] Initial starting dose; daily dosage must be titrated to gastric acid–secretory response.
[c] Duration of treatment should not exceed 14 consecutive days; if needed, repeat 14-day treatment every 4 months.

Antacids may lower the bioavailability of many orally administered drugs (e.g., digoxin, phenytoin, isoniazid, ketoconazole, itraconazole, iron preparations) that require an acidic environment for dissolution and absorption.[9,11,13] This may lead to potential therapeutic failures with these medications. Tetracyclines and fluoroquinolones are susceptible to interactions with antacids containing calcium, aluminum, or magnesium because they bind to divalent and trivalent cations.[12] The bioavailability of ciprofloxacin, for example, is reduced by more than 50% when concomitantly administered with an antacid, because aluminum and magnesium ions chelate with the antibiotic to form an insoluble and inactive complex. It is recommended to separate ciprofloxacin administration away from antacid use by 2 hours.[14] An increase in gastric pH may also result in the premature dissolution and altered absorption of enteric-coated dosage forms because the enteric coating is usually designed to dissolve at a pH greater than 6.0.[13] Urinary alkalinization may result in increased urinary excretion (salicylates) or decreased excretion (amphetamines and quinidine) leading to decreased or increased blood concentrations, respectively.[9,12] The majority of these drug interactions can be avoided by separating the antacid from the interacting drug by a minimum of 2 hours.[12]

Histamine-2 Receptor Antagonists

There are currently four H_2-receptor antagonists (H_2RAs) approved for use in the United States. These include cimetidine, ranitidine, famotidine, and nizatidine. All four agents are available in prescription and OTC dosage forms, as well as oral and parenteral formulations (nizatidine is not available parenterally in the United States). H_2RAs competitively and selectively inhibit the action of histamine on the H_2 receptors of the parietal cells, thus reducing both basal and stimulated gastric acid secretion (Fig. 23-2). Although the relative antisecretory potency on a milligram-per-milligram basis differs (famotidine has the greatest potency followed by nizatidine, ranitidine, and cimetidine), this is not an important factor because standard oral dosages of the four H_2RAs have been adjusted accordingly to have an equipotent antisecretory effect (Table 23-1).[15] Oral absorption from the small intestine is rapid, and peak drug concentrations usually are achieved within 1 to 3 hours after administration.[15] The bioavailability is lower for cimetidine, famotidine, and ranitidine because they are absorbed incompletely and undergo first-pass metabolism resulting in 40% to 65% bioavailability. The bioavailability of nizatidine is considered nearly 100% because this agent does not undergo first-pass metabolism.[15,16] All four drugs are eliminated by a combination of hepatic metabolism, glomerular filtration, and tubular secretion.[15] Hepatic metabolism is the principal pathway for the elimination of cimetidine, famotidine, and ranitidine, whereas renal excretion is the major route for elimination of nizatidine.[15–19] Dose reductions for all four agents are recommended for patients with moderate to severe renal insufficiency. The pharmacokinetics appear to be unaffected by hepatic dysfunction; however, in patients with combined hepatic failure and renal insufficiency, dosage reduction is likely necessary.[17]

H_2RAs are remarkably safe, and the frequency of severe adverse effects is low for all four drugs.[20] A meta-analysis of randomized placebo-controlled trials reported no difference in the incidence of adverse events of cimetidine versus placebo.[21] The most common adverse effects include GI discomfort (e.g., diarrhea, constipation), CNS effects (e.g., headache, dizziness, drowsiness, lethargy, confusion, psychosis, and hallucinations), and dermatologic effects (e.g., rashes).[20] The most frequent hematologic adverse effect is thrombocytopenia, which occurs in about 1% of patients but is reversible upon discontinuation of the H_2RA.[22] Although thrombocytopenia is more commonly reported with intravenous (IV) administration, it is likely that the overall incidence of H_2RA-associated thrombocytopenia is overestimated.[23] Hepatotoxicity, although uncommon, has been described primarily in patients receiving IV H_2RAs.[24] Cimetidine has demonstrated weak antiandrogenic effects, and its use in high doses (hypersecretory conditions) has been associated with gynecomastia and impotence in men. This effect is reversible with discontinuation of the medication or by switching to another H_2RA.[20,25] Patients at highest risk of experiencing any of these adverse effects include the elderly, those requiring higher doses (usually parenteral), and those with altered renal function.[25,26]

Similar to antacids, all four H_2RAs can potentially alter the absorption and reduce the bioavailability of drugs that require an acidic environment for absorption. The most important of these interactions is with ketoconazole, which requires an acidic pH for dissolution and absorption, potentially resulting in therapeutic failure of the antifungal.[13] Cimetidine has the greatest potential to cause drug interactions because of its ability to potently inhibit several hepatic cytochrome P-450 (CYP450) isoenzymes. The greatest concern is with those agents that have a relatively narrow therapeutic window (e.g., theophylline, lidocaine, phenytoin, quinidine, and warfarin).[13] Although ranitidine is more potent on a molar basis, it binds less intensely to the CYP450 isoenzyme system than cimetidine. Thus, when used in equipotent doses, there is less potential for interactions. Famotidine and nizatidine do not bind appreciably to the CYP450 system and do not interact with drugs that are metabolized through this hepatic system.[13] Because H_2RAs undergo renal tubular excretion, there is a potential for competition with other medications.[27] Cimetidine and ranitidine inhibit the tubular secretion of procainamide by as much as 44%, but famotidine does not have this effect.[28] Tachyphylaxis or tolerance has been described with all H_2RAs because of upregulation of the H_2 receptor site. It appears to occur more frequently with high-dose parenteral formulations but has also been described with oral therapy.[26,29] Tolerance to the antisecretory effect may develop after several days of regularly scheduled (continuous) use but can be avoided by taking the H_2RA only when needed.[30]

Proton-Pump Inhibitors

PPIs are highly specific inhibitors of gastric acid secretion and include omeprazole, lansoprazole, rabeprazole, pantoprazole, esomeprazole, and dexlansoprazole. These agents are substituted benzimidazoles and act by irreversibly binding to the H^+/K^+-ATPase (proton pump). PPIs are the most potent inhibitors of gastric acid secretion in that they inhibit the terminal step in the acid production cycle.[31–33] They inhibit both basal and stimulated gastric acid secretion in a dose-dependent and sustained fashion.[32] PPIs are prodrugs and require an acidic environment for conversion to the active sulfonamide. They are absorbed in the small intestine (protected from the acidic milieu of the stomach by enteric coating) and taken via the bloodstream to the acidic secretory canaliculus of the parietal cell for protonation to the active form (Fig. 23-2).[31,33] This conversion requires an actively secreting proton pump, and hence, these agents are most efficacious when taken 30 to 60 minutes before a meal on an empty stomach.[33] The most recent PPI, dexlansoprazole MR (modified release), differs from others in this class in that they use dual delayed-release technology, which extends the duration of their antisecretory effect. Dexlansoprazole MR contains two different pH-dependent granules. The first of these is initially released in the proximal duodenum similar to the other PPIs, followed by a second release of drug in the distal small intestine approximately 4 hours later. Given this broadened duration of drug exposure, dexlansoprazole MR may also be taken without regard to meal times.[34] Despite the short plasma elimination half-lives (~1–2 hours) of the other PPIs, the duration of their antisecretory effect is 48 to 72 hours because of covalent (irreversible) binding to the proton pump.[33,35] PPIs have similar acid-inhibitory effects and healing rates when used in equivalent doses (Table 23-1).[36–41] PPIs are superior to H_2RAs in reducing gastric acid secretion and mucosal healing.[35,41,42] Dosage reduction is not required in patients with renal insufficiency but is recommended for patients with severe hepatic impairment.[43]

The oral PPIs are formulated as delayed-release enteric-coated granules within capsules (omeprazole, lansoprazole, esomeprazole, dexlansoprazole MR), delayed-release enteric-coated tablets (pantoprazole, rabeprazole, OTC omeprazole), a rapidly disintegrating tablet (lansoprazole), delayed-release oral suspension (lansoprazole), and an immediate-release formulation (omeprazole and sodium bicarbonate capsules and powder for oral suspension).[36] IV formulations in the United States include pantoprazole and esomeprazole. Various methods of administration, specific dosage forms, and compounding options for patients with special needs (e.g., dysphagia, gastric tubes) will be discussed later in this chapter (see section on Upper Gastrointestinal Bleeding).

The short-term adverse effects of PPIs are relatively infrequent and comparable with H_2RAs or placebo. The most common side effects include GI discomfort (e.g., nausea, diarrhea, abdominal pain), CNS effects (e.g., headache, dizziness), and rare isolated reactions (e.g., skin rash, increased liver enzymes).[31,44] The immediate-release formulation of omeprazole contains sodium bicarbonate, and care should be taken in sodium-restricted patient populations, as discussed in the subsection Antacids and Alginic Acid of the Pharmacotherapy of Drugs Used to Treat Acid-Related Disorders. All PPIs are metabolized by the hepatic CYP450 microenzyme system. Omeprazole and esomeprazole have been described as inhibiting CYP2C19 and decreasing the clearance of diazepam, phenytoin, and R-warfarin, whereas lansoprazole increases the metabolism of theophylline by inducing CYP1A.[33,45] Although the clinical importance of these interactions is thought to be negligible, care should be taken when combining these agents to prevent possible toxicity or therapeutic failure.

The potential CYP2C19 interaction with the PPIs and the thienopyridine antiplatelet drug clopidogrel has generated a substantial amount of interest and debate. In 2008, consensus guidelines developed by the American College of Cardiology, the American Heart Association, and American College of Gastroenterology recommended the prophylactic use of PPIs in patients receiving concomitant dual antiplatelet therapy with aspirin and clopidogrel to reduce the risk of upper GI bleeding.[46] Since the publication of this document, there have been numerous reports suggesting an interaction between PPIs and clopidogrel, which attenuates the antiplatelet effects of clopidogrel and potentially increases the risk of adverse cardiovascular outcomes.[47–51] The hypothesis for this interaction is based on the requirement of clopidogrel to undergo biotransformation through CYP2C19 for conversion from prodrug to active metabolite. Because PPIs also require this metabolic pathway for metabolism, it has been suggested in pharmacokinetic and pharmacodynamic studies that concurrent use of PPIs may inhibit or compete for this enzyme, leading to a reduction in the conversion of clopidogrel to its active metabolite and, therefore, a reduction in its efficacy toward platelet inhibition.[48–51] Cardiovascular outcomes' studies involving a plethora of observational designs have suggested higher cardiovascular event rates (composite ischemic endpoints, all-cause mortality, nonfatal myocardial infarctions, stroke, and stent thrombosis).[51]

One important confounding variable involved in the evaluation of this interaction is the role played by genetic polymorphisms in CYP2C19—these can result in loss of functional alleles, which has been related to decreased clopidogrel effectiveness as a result of reduced ability to convert clopidogrel to the active metabolite responsible for platelet inhibition.[52] Upon review of this body of evidence, the US Food and Drug Administration (FDA) in 2009 issued a labeling change for clopidogrel and a safety warning recommending providers to avoid the coadministration of omeprazole, omeprazole/sodium bicarbonate, or esomeprazole with clopidogrel.[53] An update to the 2008 consensus document has attempted to critically evaluate the evidence regarding the interaction and give direction for health-care providers.[54] Although this document has taken a more cautious approach, suggesting that a likely interaction may exist especially between clopidogrel and omeprazole, data supporting definitive adverse clinical outcomes as a result of the interaction are limited to observational data. Also, the consensus document suggests there is no evidence to suggest switching from one PPI to another or that separating the timing of doses has any clear benefit on reducing the magnitude of the interaction.[54] A meta-analysis including more recently published, randomized controlled trials evaluating this drug interaction found conflicting results, whereas aggregate results from randomized controlled trials showed no difference in cardiovascular outcomes.[55] Until more comprehensive evidence becomes available, the most important aspects to consider are to ensure that patients have an appropriate indication for the use of a PPI, to determine that on a case by case basis the benefit outweighs the risk, and, if possible, to avoid concomitant use of omeprazole or esomeprazole with clopidogrel unless absolutely necessary.

An increase in intragastric pH may increase the bioavailability of orally administered medications (e.g., digoxin, nifedipine), leading to the possibility of toxicity, or it may decrease the absorption of ketoconazole and cefpodoxime, increasing the possibility of therapeutic failure.[33,45]

PPIs have been associated with a number of adverse effects when used long term and in high dosages.[56,57] However, in most cases, there is insufficient evidence to support a causal relationship between the PPI and the effect. There is evidence to suggest a relationship between elevated serum gastrin concentrations and ECL hyperplasia as a result of the PPIs' profound ability to inhibit gastric acid secretion. It has been hypothesized that this can progress to gastric carcinoid tumors (a precursor of gastric cancer). Although ECL hyperplasia has been described with the use of PPIs, there is no clinical evidence to suggest that long-term (>10 years) therapy progresses to a higher grade of hyperplasia or gastric ECL carcinoid.[58] Atrophic gastritis has been observed in gastric corpus biopsies from patients treated long term with omeprazole and positive for Helicobacter pylori. However, review of the data by the FDA has been inconclusive and not able to show causality among long-term use of PPIs, H. pylori, and atrophic gastritis.[56–58]

PPIs have been associated with an increased risk of infections (e.g., pneumonias, enteric infections) possibly because of the ability of the microorganisms to survive in a less acidic environment.[56–60] Acute nosocomial infections (pneumonia) associated with critically ill patients will be described later when discussing high-dose oral and parenteral PPI therapy (see section on Upper Gastrointestinal Bleeding). The risk of development of community-acquired pneumonia in patients treated with PPIs has also been evaluated in numerous retrospective studies; however, causality has been very difficult to establish and remains controversial.[57] Enteric infections and cancer have also been described as a result of potential bacterial overgrowth. The most common pathogens are Clostridium difficile, Salmonella typhimurium, and Campylobacter jejuni; however, data suggest that they rarely lead to illness.[59–60] A retrospective database study of PPI use describes a near threefold increase in the risk of C. difficile–associated diarrhea in patients receiving PPIs versus patients not on a PPI, but the overall risk remains low and should not be considered a contraindication to therapy.[61] Results from two published meta-analyses totaling ~300,000 patients enrolled into observational studies suggest that PPI users are at a greater than 65% risk increase of developing C. difficile–associated diarrhea.[61,62]

Long-term PPI use in older patients on high dosages has also been associated with an increased risk of hip fractures through the presumed inhibition of calcium absorption by PPI-induced hypochlorhydria or through inhibition of proton pumps within the osteoclastic vacuole resulting in decreased bone resorption.[56,63] Long-term PPI use has also been modestly associated with fractures of the spine, forearm, and wrist.[63] In a large retrospective cohort study of 8,400 patients, PPI therapy was not associated with any significant acceleration in bone-mineral density loss after 5 and 10 years of follow up. Additional studies are required to confirm a causal relationship between long-term PPIs and bone fractures, and at this time, additional bone density testing and calcium supplementation are not suggested beyond age-related recommendations.[60,64–67]

A decrease in vitamin B_{12} (cyanocobalamin) has been described in patients with long-term PPI use and may occur because gastric acid is required to liberate the vitamin from dietary sources.[56–58,67] In a large retrospective case-controlled study, long-duration PPI usage (greater than 2 years) was associated with an increased odds ratios of 1.65 (95% CI: 1.58–1.73). There was also a dose relationship, where high doses were associated an increased odds ratio of 1.95 (95% CI: 1.77–2.15).[67] Hypomagnesemia may occur in adults taking PPIs for longer than 1 year, but cases have been reported after 3 months of treatment.[68–70] This relationship has been confirmed in two retrospective studies in ambulatory care patients. The exact mechanism by which PPIs increase the risk of hypomagnesemia is uncertain but may be associated with altered intestinal absorption of magnesium. Malabsorption of iron secondary to long-term gastric acid suppression has been suggested but has not been confirmed in clinical trials.[56,57] PPIs have been associated with interstitial nephritis, but this is an extremely rare finding.[57,71] Although the long-term effects associated with PPIs are uncommon, the benefit of long-term use must always be weighed against potential risks in each individual patient.

Sucralfate

Sucralfate (an aluminum salt of a sulfated disaccharide) promotes gastric mucosal protection by shielding ulcerated tissue from aggressive factors, such as acid, pepsin, and bile salts.[72] At a pH of 2.0 to 2.5, sucralfate binds to damaged and ulcerated mucosa, forming a physical barrier against injury from these aggressive factors. The drug has minimal systemic absorption and does not possess antisecretory activity. Sucralfate may also have other protective actions related to the stimulation of mucosal prostaglandins.[72] The most common side effect associated with sucralfate is constipation, which occurs in approximately 1% to 3% of patients.[72] This is most likely attributable to the aluminum content of the compound, which can accumulate in patients with renal insufficiency. Therefore, long-term use should be avoided.[72] Additionally, aluminum salts can bind with dietary phosphate in the GI tract, the potential for hypophosphatemia exists (see subsection on Antacids and Alginic Acid of the section Pharmacotherapy of Drugs Used to Treat Acid-Related Disorders). Sucralfate tablets are large, and some patients, particularly the elderly, may have difficulty swallowing them. A liquid formulation is available for patients with swallowing difficulties. The bioavailability of oral fluoroquinolones, warfarin, phenytoin, levothyroxine, quinidine, ketoconazole, amitriptyline, and theophylline may be reduced when concomitantly administered with sucralfate.[13] The mechanism of these interactions is thought to be caused by binding of the medication with sucralfate in the GI tract, thus, limiting their absorption. Because of these interactions, sucralfate should be given at least 2 hours after these medications.

Misoprostol

Misoprostol, a synthetic prostaglandin E_1 analog, is the only prostaglandin analog approved for use in the United States. Misoprostol acts primarily by enhancing mucosal defense mechanisms.[73] It produces cytoprotective effects by stimulating the production of mucus and bicarbonate, improving mucosal blood flow, and reducing mucosal cell turnover similar to the effects of endogenous prostaglandin.[73] Misoprostol also produces a dose-dependent inhibition of gastric acid, but even at high doses, the inhibition is less than that of H_2RAs. The use of misoprostol is limited because of its potential to cause dose-dependent diarrhea (in up to 30% of patients) and abdominal cramping.[73] Taking the drug with meals may help to reduce the incidence of diarrhea. Decreasing the daily dose may also reduce diarrhea, but efficacy may be compromised[74] (see section on Peptic Ulcer Disease). Other troublesome side effects include nausea, flatulence, and headaches. Misoprostol is an abortifacient because of its uterotropic effects. Thus, it is contraindicated in pregnant women.[73,75] Use in women in their childbearing years requires a negative serum pregnancy test and adequate contraception.

Bismuth Salts

Bismuth subsalicylate has been used for years as an OTC option for many GI ailments. Although its mechanism of action is not completely understood, bismuth is thought to work by binding to and protecting mucosal lesions and enhancing cellular protective mechanisms. Bismuth also has an antimicrobial effect, primarily against H. pylori.[76] Bismuth salts have no acid-inhibitory effects. Bismuth-containing products have few side effects, but there is a decrease in drug elimination in patients with renal impairment. Bismuth subsalicylate should be used with caution in patients on concomitant salicylates because the potential exists for salicylate toxicity or increased bleeding risk. Patients with salicylate allergies or sensitivities should also be warned of the salicylate component. Long-term use is also not advised. Bismuth salts are associated with a harmless black coloring of the stools because of colonic conversion of bismuth to bismuth sulfide and a potential black discoloration of the tongue with liquid dosage forms.[8] Bismuth subcitrate potassium (biskalcitrate) is only available as a combination product with metronidazole and tetracycline for the treatment of H. pylori infection[77] (see section on Peptic Ulcer Disease). Although side effects are similar to bismuth subsalicylate, it has the advantage of not containing salicylate.

DYSPEPSIA

Dyspepsia refers to a subjective feeling of pain or discomfort located primarily in the upper abdomen and is a common problem that affects about 25% of the U.S. population.[78,79] The etiology of dyspepsia can be secondary to an organic disease, such as PUD, GERD with or without esophagitis, and gastric malignancy, or drug induced from medications such as nonsteroidal anti-inflammatory drugs (NSAIDs), antibiotics, such as erythromycin and tetracycline, iron and potassium supplements, digoxin, theophylline, and bisphosphonates. Smoking or a stressful lifestyle can also play a role in dyspepsia (Fig. 23-3). With chronic dyspepsia, patients usually have intermittent symptoms lasting a long time despite periods of remission. Heartburn may coexist with dyspepsia but is usually suggestive of GERD.

Patients who have not undergone diagnostic testing are referred to as having “uninvestigated” dyspepsia, whereas those who have undergone testing (usually upper endoscopy) are said to have “investigated” dyspepsia (Fig. 23-3). Functional dyspepsia, also known as idiopathic or non-ulcer dyspepsia (NUD), is a clinical syndrome in which there is no evidence of mucosal damage related to PUD, GERD, or malignancy found at endoscopy.

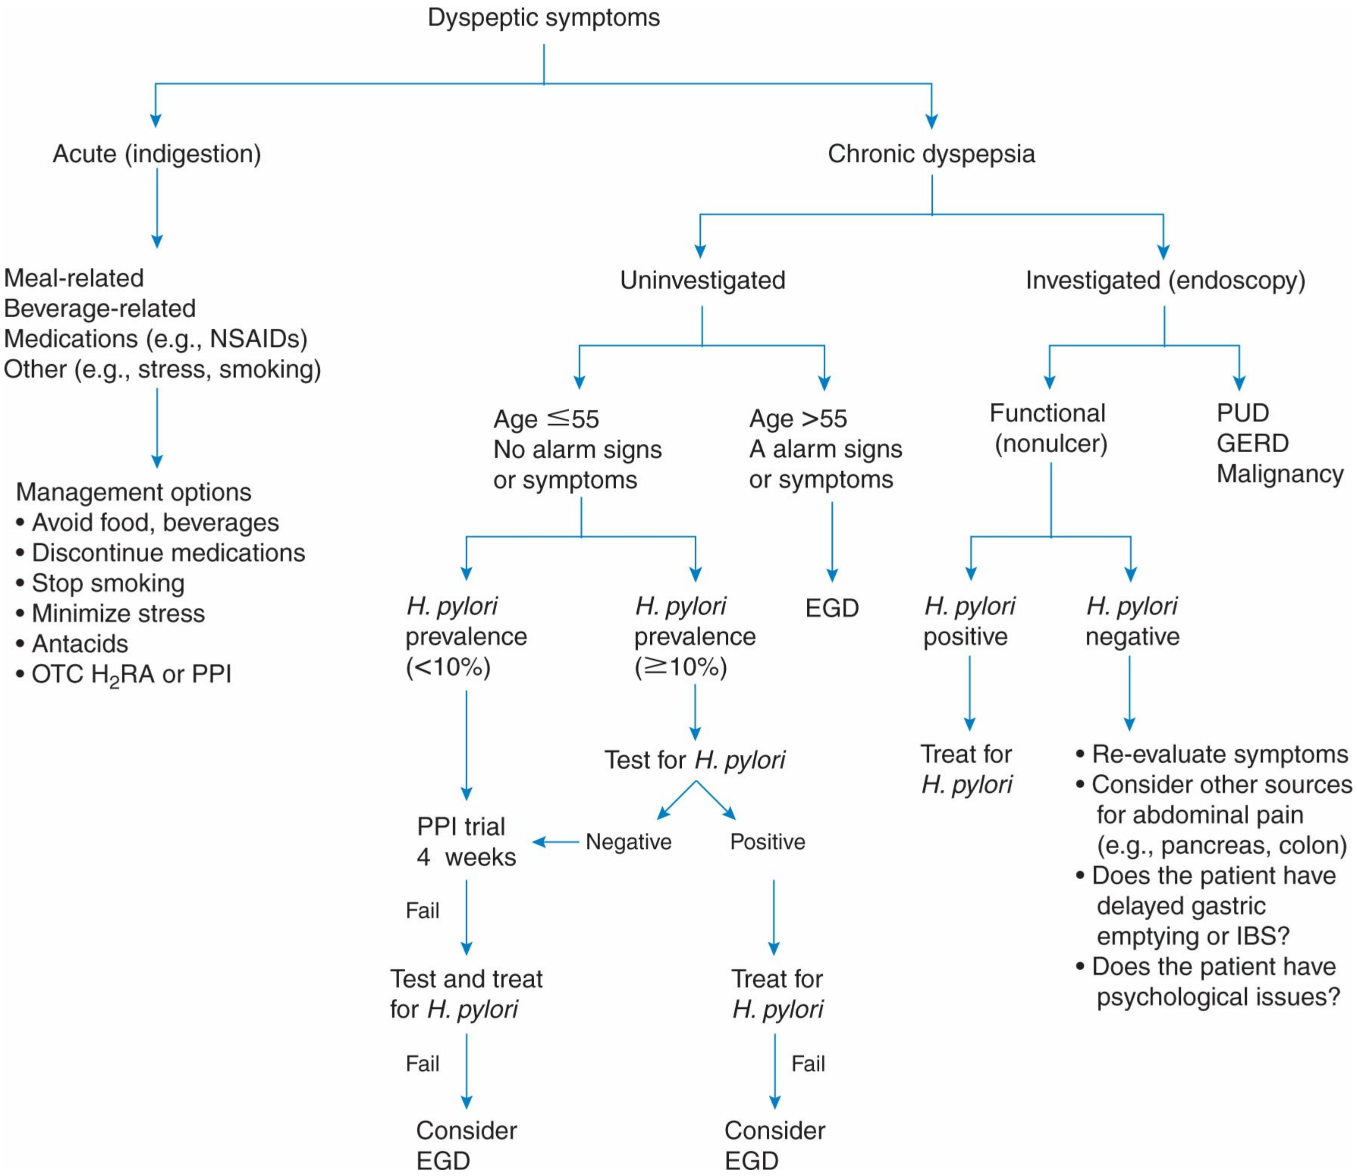
Functional dyspepsia is defined based on the ROME III diagnostic criteria. It includes the presence of one or more of the following symptoms for the last 3 months with symptom onset 6 months before diagnosis and no evidence of structural anatomic symptoms.[80,81]

- Postprandial fullness (classified as postprandial distress syndrome)
- Early satiation (inability to finish a normal-sized meal, also classified as postprandial distress syndrome)
- Epigastric pain or burning (classified as epigastric pain syndrome)

Pathophysiology

Acute, infrequent dyspepsia is most often related to food, alcohol, smoking, or stress.

Chronic dyspepsia may be related to an underlying cause, such as PUD, GERD, or malignancy, or may not have any known cause (endoscopy-negative, functional, idiopathic dyspepsia). About 40% of patients with functional dyspepsia have pathophysiologic disturbances that involve delayed gastric emptying.[81] There is also evidence that the esophagus, stomach, duodenum, and other regions of the GI tract are hypersensitive and may be associated with irritable bowel syndrome, especially in women.[81] Others have failed to find a pathologic association between functional dyspepsia and gastroduodenal motility, hypersensitivity, or any other GI abnormality, and suggest that psychologic disturbances are an important contributing factor. Although H. pylori infection has been identified in 20% to 60% of patients with functional dyspepsia, its pathophysiologic relevance remains uncertain.[80]



Dyspeptic symptoms
Acute (indigestion)
Chronic dyspepsia
Meal-related
Beverage-related
Medications (e.g., NSAIDs)
Other (e.g., stress, smoking)
Management options
• Avoid food, beverages
• Discontinue medications
• Stop smoking
• Minimize stress
• Antacids

Clinical Assessment and Diagnosis

Acute, infrequent dyspepsia is usually self-limiting and generally requires no further investigation. Chronic dyspeptic symptoms cannot be used to predict endoscopic findings of PUD, GERD, or malignancy in patients with uninvestigated dyspepsia.[81–83] In addition, individual symptoms or symptom subgroups, such as PUD-like, GERD-like, or dysmotility-like dyspepsia are not useful in distinguishing organic disease from functional dyspepsia nor does it appear to aid in management. This is because there is considerable overlap of symptoms among patients with PUD, GERD, malignancy, and functional dyspepsia.

The clinical assessment of uninvestigated dyspepsia in patients younger than or 55 years of age with no alarm signs or symptoms includes a test-and-treat H. pylori option, which is preferable in geographic areas of moderate to high prevalence of H. pylori infection (≥10%)[81] (Fig. 23-3). H. pylori testing should be conducted by using a nonendoscopic-validated test (see section on Tests for Detecting Helicobacter pylori). New-onset dyspepsia in an older individual is considered an independent risk factor for an underlying malignancy such as gastric cancer.[81] Dyspeptic patients older than 55 years of age or those with alarm signs or symptoms should undergo upper endoscopy (Fig. 23-3). Other alarm features that assist in identifying serious underlying diseases, especially malignancy, include early satiety, anorexia, worsening dysphagia or odynophagia, unexplained weight loss (>10% body weight), vomiting, anemia, GI bleeding, lymphadenopathy, jaundice, a history of PUD, a family history of upper GI tract cancer, previous gastric surgery, or malignancy.[81] Although a symptom duration threshold has not been established, a long history of symptoms or antisecretory drug use may suggest a serious underlying condition.

Treatment

The recommended strategies for managing dyspepsia in adults are presented in Figure 23-3. Individuals with acute dyspepsia can be effectively treated with self-directed therapy using antacids or OTC antisecretory drugs if they are unable or unwilling to avoid offending foods and beverages, stop smoking, or discontinue troublesome medications. The initial management of patients younger than or 55 years of age with uninvestigated chronic dyspepsia and no alarm features depends on the prevalence of H. pylori and whether the patient is H. pylori positive or H. pylori negative (Table 23-2). Empiric therapy with a PPI for 4 weeks is considered first-line treatment and cost-effective in areas with a low prevalence of H. pylori and in patients who are H. pylori negative.[81–83] PPIs should be discontinued after 1 month if the patient's symptoms respond to treatment. If symptoms recur, then long-term PPI therapy may be considered, but the need for a PPI should be evaluated every 6 to 12 months.[80] Endoscopy is advocated for patients who fail to respond to an initial 4 to 8 weeks of empiric PPI therapy and those whose symptoms continue to recur after stopping the PPI (Fig. 23-3).[80,81] Patients who are H. pylori positive should receive a PPI-based eradication regimen[80–83] (see section on Helicobacter pylori–Related Ulcers).

Early endoscopy with biopsy for H. pylori is recommended for patients older than 55 years of age with uninvestigated chronic dyspepsia and those with alarm features. In the event that an abnormality (such as PUD, GERD, or malignancy) is found, it should be treated accordingly. The medical management of functional dyspepsia (e.g., NUD) is challenging and, when possible, should take into consideration the cost-effectiveness of treatment.[81–83] Although pharmacotherapy is considered for most patients, evidence of benefit is limited because of the lack of well-designed studies and an incomplete understanding of the disorder. Meta-analyses have demonstrated the efficacy of H_2RAs and PPIs, but there is no evidence to support the use of antacids, sucralfate, and misoprostol.[84] There appears to be no difference in efficacy between full-dose or double-dose PPIs.[84] An economic review suggests that PPIs are cost-effective for functional dyspepsia in the United States.[85] The impact of H. pylori eradication in functional dyspepsia remains limited, in part, because of the lack of short-term symptomatic benefit and because of the steadily declining prevalence of H. pylori in the United States.[82] An updated meta-analysis, however, reports a small therapeutic gain with eradication when compared with placebo at 12 months of follow up.[86] Although the benefit of prokinetics have been reported, most studies were conducted with cisapride, which was withdrawn from the U.S. market.[84] The use of available prokinetics (metoclopramide and erythromycin) should be reserved for difficult-to-treat patients because of their side effects and limited efficacy.[81,83] New guidelines also recommend against the combination of prokinetics and H_2RAs because the combination was not shown to be more effective than either agent alone and is usually not used unless there is the presence of gastroparesis. Antidepressants, especially the tricyclics, are often prescribed in functional dyspepsia and may have some benefit; however, the mechanism for this finding is unclear, and published clinical trials are small and of poor quality resulting in uncertain efficacy.[81,83,84] Alternative therapies, including herbal products, remain unproven.[81] Patients with persistent dyspepsia despite a negative endoscopy, in whom PPI therapy and H. pylori eradication fails, should have their diagnosis reevaluated.

Table 23-2

Indications for Testing and Treating Helicobacter pylori Infection

Recommended (Evidence Established)
■ Uninvestigated dyspepsia (depending on H. pylori prevalence) ■ PUD (active gastric or duodenal ulcer)

- History of PUD (confirmed ulcer not previously treated for H. pylori)
- Gastric MALT lymphoma
- After resection of early gastric cancer
- Reduce the risk of recurrent bleeding from gastroduodenal ulcer

Controversial (Evidence Not Well Established)

- NUD
- Individuals using NSAIDs (no signs/symptoms of peptic ulcer)
- GERD
- Individuals at risk for gastric cancer
- Individuals with unexplained iron deficiency anemia

GERD, gastroesophageal reflux disease; MALT, mucosa-associated lymphoid tissue; NUD, non-ulcer dyspepsia; NSAID, nonsteroidal anti-inflammatory drug; PUD, peptic ulcer disease.

PEPTIC ULCER DISEASE

PUD is one of the most common gastroenterologic diseases affecting the upper GI tract.[87] Chronic peptic ulcers are defects in the gastric (gastric ulcer) or duodenal (duodenal ulcer) mucosa that require gastric acid for their formation. Chronic peptic ulcers differ from erosions and gastritis in that the ulcer extends deeper into the muscularis mucosa.[87,88]

Stress ulcer is an acute form of peptic ulcer, but it occurs primarily in critically ill patients and differs in its underlying pathogenesis (see section on Stress-Related Mucosal Bleeding).

Epidemiology

It is difficult to estimate the epidemiology of PUD because of the different methods used to diagnose peptic ulcers (e.g., symptom-based, ulcer-related complications, radiology, or endoscopy) as well as differences in NSAID use, H. pylori prevalence, and cigarette smoking. Improved medical treatment, changes in the criteria and coding for hospitalizations and mortality, and the evolution from hospital-based to ambulatory care have also altered the epidemiology of PUD.[87] Current data suggest a shift in the prevalence of PUD in the United States from predominantly men to a comparable rate in men and women.[87] A declining ulcer rate in younger individuals and an increasing rate for older adults reflect a decline in H. pylori infection and an increased use of NSAIDs in the United States. Office visits, hospitalizations, and deaths have modestly declined during the last four decades, but deaths among older patients (>75 years) have increased and are most likely related to NSAID use.[87]

Etiology and Risk Factors

H. pylori and NSAIDs are the two most common causes of chronic PUD and influence the chronicity of the disease.[87] Less common causes include hypersecretory states, such as Zollinger–Ellison syndrome (ZES) (see section on Zollinger–Ellison Syndrome), viral infections (e.g., cytomegalovirus), radiation, and chemotherapy (e.g., hepatic artery infusion).[87] Factors that may increase the risk of a peptic ulcer include alcohol ingestion; cigarette smoking; psychologic stress; corticosteroids; and chronic diseases, such as renal failure, cirrhosis, pancreatitis, obstructive pulmonary disease, Crohn disease, or organ transplantation.[87]

HELICOBACTER PYLORI–RELATED ULCERS

H. pylori infection is causally linked to chronic gastritis, PUD, mucosa-associated lymphoid tissue (MALT) lymphoma, and gastric cancer (Table 23-2).[87–92] The lifetime risk of exhibiting an endoscopic ulcer in H. pylori–positive individuals is 10% to 20%, and the risk for developing gastric cancer is 1% to 2%.[87,88,92] Differences in strain variability and host-specific factors account for the variable pathogenesis of the organism.[88,91] There is an increasing evidence that iron deficiency anemia and idiopathic thrombocytopenia are associated with H. pylori infection, but cause and effect remain unproven.[89,93] The association between H. pylori and PUD bleeding remains unclear, but H. pylori eradication decreases recurrent bleeding[89] (see section on Upper Gastrointestinal Bleeding).

The prevalence of H. pylori varies by geographic location, socioeconomic status, ethnicity, and age and is more common in developing countries than in industrialized nations.[88] The overall prevalence in the United States is estimated to be 30% to 40% but is higher in older individuals (50%–60%) than in children (10%–15%).[88] The higher prevalence among older adults reflects acquisition during infancy and early childhood. However, infection rates in the United States have been declining in children because of improved socioeconomic conditions.[88,89]

Transmission occurs usually during childhood from the infected person by either the gastro-oral (vomitus) or fecal–oral (diarrhea) route or from fecal-contaminated water or food.[88,90] Individuals living in the same household with an H. pylori–positive person, especially when there is household crowding, are at increased risk for acquiring the infection.[88,90] H. pylori can also be transmitted through the use of inadequately sterilized endoscopes.

Nonsteroidal Anti-Inflammatory Drug–Induced Ulcers

There is a considerable evidence linking the chronic use of NSAIDs with GI injury.[87,94–97] Endoscopically confirmed gastric and duodenal ulcers develop in 15% to 30% of chronic NSAID users, and 2% to 4% experience ulcer-related bleeding or perforation.[94,95] Gastric ulcer is most common and develops primarily in the antrum. NSAIDs may also cause ulcers in the esophagus and the colon, but these ulcers occur less frequently and differ in their underlying pathogenesis.[94,97] It is estimated that NSAIDs account for about 100,000 hospitalizations and 7,000 to 10,000 deaths annually in the United States, but mortality may be overstated because of the recent decline in hospitalizations.[95] A national prescription audit in the United States revealed an annual NSAID cost of $4.9 billion, with additional nonprescription NSAID sales of $3 billion.[98] The risk factors for NSAID-induced ulcers and upper GI complications are listed in Table 23-3. Combinations of factors confer an additive risk.

Table 23-3

Risk Factors for Nonsteroidal Anti-Inflammatory Drug–Induced Ulcer and Ulcer-Related Upper Gastrointestinal Complications

Established
■ Confirmed prior ulcer or ulcer-related complication
■ Age >65 years
■ Multiple or high-dose NSAID use
■ Concomitant use of aspirin (including low cardioprotective dosages, e.g., 81 mg)
■ Concomitant use of an anticoagulant, corticosteroid, bisphosphonate, clopidogrel, or SSRI
■ Selection of NSAID (selectivity of COX-1 vs. COX-2)
Controversial
■ H. pylori
■ Alcohol consumption
■ Cigarette smoking

COX-1, cyclooxygenase-1; COX-2, cyclooxygenase-2; NSAID, nonsteroidal anti-inflammatory drug; SSRI, selective serotonin reuptake inhibitor.

Pathophysiology

A physiologic balance exists in healthy individuals between gastric acid secretion and gastroduodenal mucosal defense. Peptic ulcers occur when the balance between aggressive factors (gastric acid, pepsin, bile salts, H. pylori, and NSAIDs) and mucosal defensive mechanisms (mucosal blood flow, mucus, mucosal bicarbonate secretion, mucosal cell restitution, and epithelial cell renewal) are disrupted.[87,96] Increased acid secretion may occur in patients with duodenal ulcer, but most patients with gastric ulcer have normal or reduced rates of acid secretion.[7] Pepsin is an important cofactor that plays a role in the proteolytic activity involved in ulcer formation. Mucosal defense and repair mechanisms protect the gastroduodenal mucosa from noxious endogenous and exogenous substances.[87] The viscous nature and near-neutral pH of the mucus–bicarbonate barrier protect the stomach from the acidic contents in the gastric lumen. The maintenance of mucosal integrity and repair are mediated by the production of endogenous prostaglandins. When aggressive factors alter mucosal defense mechanisms, back diffusion of hydrogen ions occurs with subsequent mucosal injury. H. pylori and NSAIDs cause alterations in mucosal defense by different mechanisms and are important factors in the formation of peptic ulcers.

HELICOBACTER PYLORI–RELATED ULCERS

H. pylori is a gram-negative, spiral-shaped bacillus that thrives in a microaerophilic environment. The bacterium resides between the mucus layer and surface epithelial cells in the stomach or any location where gastric-type epithelium is found.[88] Flagella enable it to move from the lumen of the stomach, where the pH is low, to the mucus layer, where the pH is neutral. Acute infection is accompanied by transient hypochlorhydria, which enables the organism to survive the acidic gastric juice. Although the exact method by which H. pylori induces hypochlorhydria is uncertain, it is hypothesized that its urease-producing ability hydrolyzes urea in the gastric juice and converts it to ammonia and carbon dioxide, which creates a neutral microenvironment that surrounds the bacterium.[88,96] Adherence pedestals attach to gastric-type epithelium and prevent the bacterium from being shed during cell turnover and mucus secretion.

Disease outcome depends on the patterns of H. pylori colonization and inflammation within the stomach.[88,96] Colonization of the antrum and acid-secreting body (corpus) of the stomach is associated with gastric ulcer and gastric adenocarcinoma and is typically accompanied by gastric atrophy and decreased acid secretion. When H. pylori colonizes, the antrum and the body of the stomach are spared, the risk for duodenal ulcer is increased, and gastric acid is normal or slightly increased. Ulcers in the duodenum arise from the colonization by antral organisms of gastric-type epithelium that develops in the duodenum in response to changes in duodenal pH.[88]

Direct mucosal damage is produced by virulence factors (e.g., cytotoxin-associated gene, vacuolating cytotoxin), elaborating bacterial enzymes (e.g., urease, lipases, proteases), and adherence.[88,96,99] Cytotoxin-associated gene A (CagA) protein occurs in about 60% of H. pylori strains in the United States and is associated with severe gastritis, peptic ulcers, and gastric cancer when compared with CagA-negative strains.[88,96,99] Although vacuolating cytotoxin A (VacA) is present in almost all H. pylori strains, differences in cytotoxic activity are related to variations in the VacA gene structure and are associated with an increased risk for PUD and possibly gastric cancer.[88,99] H. pylori infection may also cause alterations in the host immune response.[88,99] Host polymorphisms related to interleukin (IL)-1β and its receptor antagonist, tumor necrosis factor α (TNF-α), and IL-10, may be associated with increased gastric acid secretion and duodenal ulcer or acid suppression and gastric cancer.[88,99]

Nonsteroidal Anti-Inflammatory Drug–Induced Ulcers

Nonselective NSAIDs (Table 23-4), including aspirin, cause peptic ulcers and upper GI complications by systemically inhibiting protective prostaglandins in the gastric mucosa.[87,94,96] NSAIDs inhibit cyclooxygenase (COX), the rate-limiting enzyme in the conversion of arachidonic acid to prostaglandins. There are two COX isoforms: COX-1, which is found in the stomach, kidney, intestine, and platelets, and COX-2, which is induced with acute inflammation.[87,94] The inhibition of COX-1 is associated with upper GI and renal toxicity, and the inhibition of COX-2 is related to anti-inflammatory effects.[87,94] Nonselective NSAIDs, including aspirin, inhibit both COX-1 and COX-2 to varying degrees and decrease platelet aggregation, which may increase the risk for upper GI bleeding.[87,94] The coadministration of selected NSAIDs (e.g., ibuprofen) with aspirin also reduces the antiplatelet effects of aspirin.[46] Although prostaglandin inhibition is regarded as the major cause of gastric ulcers, diversion of arachidonate through the lipoxygenase pathway enhances leukotriene synthesis and results in vasoconstriction and release of oxygen free radicals, which may also contribute to impairment of mucosal defense.[94] There is an increasing evidence that NSAIDs may cause gastric damage by interfering with the mucosal synthesis of nitric oxide and hydrogen sulfide, important mediators in maintaining gastric mucosal intergrity.[94]

The relative COX selectivity among NSAIDs varies and is thought to be an important factor in determining the propensity for ulcer formation.[87,94] Thus, certain NSAIDs may be more COX-1–sparing than others (e.g., the partially selective NSAIDs; Table 23-4) and may be associated with less GI toxicity, but there are few controlled trials to support this claim.[87,94,100,101] COX-2 inhibitors, such as rofecoxib and valdecoxib (Table 23-4), do not inhibit gastric mucosal prostaglandin synthesis or serum thromboxane A_2, which accounts for their improved GI safety.[94,101] Unfortunately, both rofecoxib and valdecoxib were withdrawn from the U.S. market in 2004 because of concerns about cardiovascular safety.[87] Celecoxib, an NSAID initially marketed as a COX-2 inhibitor, currently remains available in the United States despite similar concerns about cardiovascular risk, especially at higher dosages.[87] However, the benefit of celecoxib in reducing the risk of gastric ulcer and upper GI complications may be lower than with rofecoxib and valdecoxib (Table 23-4).

Table 23-4

Selected Nonsteroidal Anti-Inflammatory Drugs

Salicylates
Acetylated: aspirin
Nonacetylated: trisalicylate, salsalate
Nonsalicylates[a]
Nonselective (traditional) NSAIDs: ibuprofen, naproxen, tolmetin, fenoprofen, sulindac, indomethacin, ketoprofen, ketorolac, flurbiprofen, piroxicam
Partially selective NSAIDs: etodolac, diclofenac, meloxicam, nabumetone
Selective COX-2 inhibitors: celecoxib[b], rofecoxib[c], valdecoxib[c]

[a] Based on COX-1/COX-2 selectivity ratio in vitro.

[b] Initially marketed as a COX-2 inhibitor, but current FDA labeling is consistent with nonselective and partially selective NSAIDs.

[c] Withdrawn from the U.S. market.

COX-2, cyclooxygenase-2; NSAID, nonsteroidal anti-inflammatory drug.

COX-2, cyclooxygenase-2; NSAID, nonsteroidal anti-inflammatory drug.

Aspirin and non-aspirin NSAIDs also have a topical (direct) irritating effect on the gastric mucosa, but the resulting inflammation and erosions usually heal within a few days. Gastric damage is associated with the acidic properties of aspirin and non-aspirin NSAIDs and their ability to decrease the hydrophobicity of the mucous gel layer in the gastric mucosa.[94,102] Thus, direct mucosal injury appears to correlate with the pK_a of a compound—suggesting the lower the acidity of the drug, the less the short-term topical damage.[94] Formulations, such as enteric-coated aspirin, buffered aspirin, NSAID prodrugs, and parenteral or rectal preparations, may spare topical effects on the gastric mucosa, but all have the potential to cause a gastric ulcer because of their systemic inhibition of endogenous prostaglandins.[87,103]

Clinical Presentation

SIGNS AND SYMPTOMS

The signs and symptoms associated with a peptic ulcer range from mild epigastric pain to life-threatening upper GI complications.[87,96] A change in the character of the pain may indicate an ulcer-related complication. The absence of epigastric pain, especially in older adults who are taking NSAIDs, does not exclude the presence of an ulcer or related complications. Although the reasons for this are unclear, they may be related to the analgesic effect of the NSAID. There is no one sign or symptom that differentiates an H. pylori–related ulcer from an NSAID-induced ulcer. Ulcer-like symptoms may occur in the absence of peptic ulceration in association with H. pylori–related gastritis or duodenitis.

COMPLICATIONS

The most serious life-threatening complications associated with chronic PUD are upper GI bleeding, perforation into the abdominal cavity or penetration into an adjacent structure (e.g., pancreas, liver, or biliary tract), and obstruction.[87,96,104,105] Ulcer-related bleeding is the most frequent complication and occurs with all types of ulcers (see section on Upper Gastrointestinal Bleeding). The incidence of ulcer-related upper GI bleeding and perforation is highest in individuals taking NSAIDs who are older than 60 years.[94,96] The bleeding may be occult (hidden), present as melena (black-colored stools), or hematemesis (vomiting of blood). Mortality is higher in patients who continue to bleed or who rebleed after the initial bleeding has stopped and in patients with a perforated ulcer.[4,5] The pain associated with perforation is typically sudden, sharp, and severe, beginning in the epigastric area but quickly spreading throughout the upper abdominal area. Gastric outlet obstruction, the least frequent complication, is caused by previous ulcer healing and scarring or edema of the pylorus or duodenal bulb and can lead to symptoms of gastric retention, including early satiety, bloating, anorexia, nausea, vomiting, and weight loss.

Clinical Assessment and Diagnosis

TESTS FOR DETECTING HELICOBACTER PYLORI

The detection of H. pylori infection can be made through gastric mucosal biopsies in patients undergoing upper endoscopy or by nonendoscopic tests (Table 23-5).[88,89,106] The selection of a specific method is influenced by the clinical circumstance and the availability and cost of the individual test. Endoscopic tests require a mucosal biopsy for the rapid urease test, histology, or culture. Medications that reduce urease activity or the density of H. pylori may decrease the sensitivity of the rapid urease test by up to 25%.[89] For this reason, when possible, antibiotics and bismuth salts should be withheld for 4 weeks, and H_2RAs and PPIs for 1 to 2 weeks before endoscopic testing. Patients who are taking these medications at endoscopy will require histology in addition to the rapid urease test. At least three biopsies are taken from different areas of the stomach because patchy distribution of H. pylori can result in false-negative results. Acute ulcer bleeding at the time of testing is likely to decrease the sensitivity of the rapid urease test and histology and increase the likelihood of false-negative results.[89,107]

Table 23-5

Diagnostic Tests for Helicobacter pylori Infection

Tests Using Gastric Mucosal Biopsy in Patients Undergoing Endoscopy
Rapid Urease Test
■ Tests for active H. pylori infection; >90% sensitivity and specificity. ■ In the presence of H. pylori urease, urea is metabolized to ammonia and bicarbonate resulting in an increase in pH, which changes the color of a pH-sensitive indicator. ■ Results are rapid (within 24 hours), and test is less expensive than histology or culture. ■ Withhold H_2RAs and PPIs 1–2 weeks before testing and antibiotics and bismuth salts 4 weeks before testing to reduce the risk of false negatives.
Histology
■ "Gold standard" for detection of active H. pylori infection; >95% sensitive and specific. ■ Permits further histologic analysis and evaluation of infected tissue (e.g., gastritis, ulceration, adenocarcinoma); tests for active H. pylori infection. ■ Results are not immediate; not recommended for initial diagnosis; more expensive than rapid urease test.

Culture

- Permits sensitivity testing to determine antibiotic choice or resistance; 100% specific; tests for active H. pylori infection.
- Use usually limited to patients who fail initial course of eradication therapy.

Polymerase Chain Reaction

- Detects H. pylori DNA in gastric tissue; highly specific and sensitive.
- High rate of false positives and false negatives; positive DNA does not correlate directly with presence of the organism; used primarily for research.

Nonendoscopic Tests That Do Not Use Gastric Mucosal Biopsy

Urea Breath Test

- Tests for active H. pylori infection; >95% sensitive and specific.
- Radiolabeled urea with either C^{13} or C^{14} is given orally; urease secreted by H. pylori in the stomach (if present) hydrolyzes radiolabeled urea to produce radiolabeled CO_2, which is exhaled and then quantified from the expired breath; radiation exposure is minimal.
- Withhold H_2RAs and PPIs 1–2 weeks before testing and antibiotics and bismuth salts 4 weeks before testing to reduce the risk of false negatives.
- Used to detect H. pylori before treatment and to document posttreatment eradication.
- Results usually take about 2 days; less expensive than tests that utilize gastric mucosal biopsy but more expensive than serologic tests; availability and reimbursement is inconsistent.

Antibody Detection (In-Office or Near Patient)

- Qualitative test; detects IgG antibodies to H. pylori in whole blood or fingerstick.
- Effective for primary diagnosis, but not of benefit in confirming eradication because antibodies to H. pylori remain positive for years after successful eradication of the infection.
- Results obtained quickly (usually within 15 minutes) but reduced sensitivity and specificity compared with laboratory-based tests; widely available and inexpensive.
- Results not affected by H_2RAs, PPIs, or bismuth; antibiotics given for other indications may result in a positive antibody test.

Antibody Detection (Laboratory)

- Quantitative test; detects IgG antibodies to H. pylori in serum using laboratory-based ELISA tests and latex agglutination techniques.
- More accurate than in-office tests; similar sensitivity and specificity to rapid urease biopsy and urea breath tests.
- Unable to determine if antibody is related to active or cured infection; antibody titers vary between individuals and take up to 6 months to 1 year to return to the uninfected state.
- Results not affected by H_2RAs, PPIs, or bismuth; antibiotics given for other indications may result in a positive antibody test.

Fecal Antigen Test

- An enzymatic immunoassay test that identifies H. pylori antigen in stool; sensitivity and specificity comparable to the UBT for initial diagnosis.
- H_2RAs, PPIs, antibiotics, and bismuth may cause false-negative results but to a lesser extent than the UBT.
- Considered an alternative to detecting H. pylori before treatment and documenting posttreatment eradication; patients may have a reluctance to obtain stool samples.

ELISA, enzyme-linked immunosorbent assay; H_2RA, H_2 receptor antagonist; IgG, immunoglobulin G; PPI, proton-pump inhibitor; UBT, urea breath test.

American College of Gastroenterology guideline on the management of Helicobacter pylori infection. Am J Gastroenterol. 2007;102:1808; Calvet X et al. Diagnosis of Helicobacter pylori infection. Helicobacter. 2010;15(Suppl 1):7.

Nonendoscopic tests either identify active infection or detect antibodies to H. pylori.[88,89,106] If endoscopy is not planned, these tests are a reasonable choice to determine H. pylori status as they are noninvasive, more convenient, and less expensive than the endoscopic tests. Testing should only be undertaken if eradication is planned in light of positive results. The urea breath test (UBT), the most accurate noninvasive test, detects active H. pylori infection and is also effective after eradication treatment.[88,89,106] The ^{13}carbon (nonradioactive isotope) and ^{14}carbon (radioactive isotope) tests require that the patient ingest radiolabeled urea, which is then hydrolyzed by H. pylori (if present in the stomach) to ammonia and radiolabeled bicarbonate. The radiolabeled bicarbonate is absorbed in the blood and detected in expired breath. The in-office and laboratory antibody tests are a cost-effective method to initially diagnose H. pylori infection, but because they do not differentiate between active infection and previously eradicated H. pylori, they should not be used to confirm eradication.[88,89,106] The fecal antigen test identifies H. pylori antigens in the stool and is less expensive and easier to perform than the UBT.[88,89,106] Although usually comparable with the UBT in the initial detection of H. pylori, the fecal antigen test may be less accurate when used to document eradication posttreatment. Salivary and urine antibody tests are under investigation.[106]

LABORATORY TESTS, RADIOGRAPHY, AND ENDOSCOPY

Generally, laboratory tests are not helpful in the diagnosis of PUD. Fasting serum gastrin concentrations are only recommended for patients who are unresponsive to therapy or those suspected of having a hypersecretory disease. Serum hematocrit (Hct) and hemoglobin (Hgb) and guaiac fecal occult blood tests assist in the evaluation of ulcer-related bleeding.

Gastric acid–secretory studies are not routinely performed for patients suspected of having an uncomplicated peptic ulcer. However, measurements of acid secretion are instrumental in the evaluation of patients with severe, recurrent PUD that is unresponsive to standard drug therapy. Acid secretion is expressed as basal acid output (BAO), in response to a meal (meal-stimulated acid secretion), or as maximal acid output (MAO).[7] These tests estimate the acid-secretory response under various circumstances and are measured by inserting a nasogastric tube into the stomach and aspirating the gastric contents.[7] The aspirate is estimated by titration with a basic solution of known concentration and expressed as milliequivalents of H^+ per hour. Results obtained for an individual patient is then compared with standard ranges for each test. The BAO, meal-stimulated acid secretion, and MAO vary according to age, sex, health, and time of day. The BAO follows a circadian rhythm, with the highest acid secretion occurring at night and the lowest in the morning. An increase in the BAO/MAO ratio suggests a basal hypersecretory state such as ZES.

Confirmation of a peptic ulcer requires visualizing the ulcer by either GI radiography or upper endoscopy.[87] Radiography is sometimes the initial diagnostic procedure because it is less expensive than endoscopy and more widely available, but small ulcers are often difficult to detect and false positives may result from trapped barium.[87] Fiber-optic upper endoscopy (esophagogastroduodenoscopy [EGD]) is the gold standard because it detects greater than 90% of peptic ulcers and permits direct inspection, biopsy, and visualization of superficial erosions and sites of active bleeding. Upper endoscopy is preferred if complications are suspected or if an accurate diagnosis is required. If a gastric ulcer is found on radiography, malignancy should be excluded by direct endoscopic visualization and histology.

Clinical Course and Prognosis

The natural history of PUD is characterized by periods of exacerbations and remissions unless the underlying cause is removed.[87]H. pylori and NSAIDs are the two most important risk factors for the development of peptic ulcer.[87] Successful eradication of H. pylori heals ulcers and dramatically decreases ulcer recurrence and GI complications.[87] The risk for NSAID-induced ulcer and life-threatening GI complications is greatest in the elderly and those with a history of PUD. Prophylactic co-therapy or the use of a selective COX-2 inhibitor markedly decreases ulcer risk and complications.[94,95] Gastric cancer in H. pylori–infected individuals develops slowly during 20 to 40 years and is associated with a slightly higher lifetime risk when compared with that in patients with duodenal ulcer or in the general population.[88,91,92]

Treatment

THERAPEUTIC GOALS

The therapeutic goals for treating PUD in adults depend on whether the ulcer is related to H. pylori or associated with an NSAID. Treatment goals may differ depending on whether the ulcer is initial or recurrent and whether complications have occurred. Treatment is aimed at relieving ulcer symptoms, healing the ulcer, preventing ulcer recurrence, and reducing ulcer-related complications. When possible, the most cost-effective drug regimen should be utilized.

NONPHARMACOLOGIC THERAPY

Patients with PUD should discontinue NSAIDs (including aspirin) if possible. Patients unable to tolerate certain foods and beverages (e.g., spicy foods, caffeine, and alcohol) may benefit from dietary modifications. Encourage lifestyle modifications like stress reduction and decreasing or stopping tobacco use.

Probiotics, especially strains of lactic acid–producing bacteria, such as Lactobacillus and Bifidobacterium; lactoferrin; and certain foods (e.g., cranberry juice, ginger, chili, oregano, some milk proteins) have been used to supplement H. pylori eradication.[87,108–110] Animal and in vitro data have shown that probiotics have both bactericidal and protective effects, but meta-analyses of clinical trials suggest only a slight improvement in eradication rates.[87,108,109] Lactoferrin, a member of the transferrin family, has been reported to inhibit H. pylori attachment to gastric epithelial cells.[110] Although certain strains of Lactobacillus and Bifidobacterium or lactoferrin may enhance eradication, they are not effective as single agents. Additional clinical trials are necessary before probiotics or lactoferrin are routinely recommended as supplements to H. pylori regimens.

Patients with ulcer-related complications may require surgery for bleeding, perforation, or obstruction.[105] Surgery for medical treatment failures (e.g., vagotomy with pyloroplasty or vagotomy with antrectomy) is rarely performed because of effective medical management and the risk of postoperative complications from surgery.

PHARMACOTHERAPY

Drug regimens used to eradicate H. pylori are identified in Table 23-6. Recommended first-line treatment in the United States includes PPI-based three-drug regimens or a bismuth-based four-drug regimen (Fig. 23-4). However, there is a controversy as to whether sequential therapy should replace the standard PPI-based triple drug regimen as first-line treatment. If initial eradication fails, a second course of therapy should be based on the selection of antibiotics that have not been previously used. Successful treatment eradicates the infection and heals the ulcer. Treatment for H. pylori–positive patients with a conventional antiulcer drug or combining an antisecretory drug with sucralfate is not recommended because of high rates of ulcer recurrence and complications. Maintenance therapy with a PPI or H_2RA (Table 23-1) should only be necessary in high-risk patients with a history of ulcer complications, those with H. pylori–negative ulcers, and patients with other concomitant acid-related diseases (e.g., GERD).

Table 23-6

Oral Drug Regimens Used to Eradicate Helicobacter pylori Infection

Drug Regimen	Dose	Frequency	Duration
Proton-Pump Inhibitor–Based Three-Drug Regimens			
PPI	Standard dose[a]	BID[a]	14 days[b]
Clarithromycin	500 mg	BID	14 days[b]
Amoxicillin[c]	1 g	BID	14 days[b]
Or			
PPI	Standard dose[a]	BID[a]	14 days[b]
Clarithromycin	500 mg	BID	14 days[b]
Metronidazole[c]	500 mg	BID	14 days[b]
Bismuth-Based Four-Drug Regimens			
Bismuth subsalicylate[d]	525 mg	QID	10–14 days
Metronidazole	250–500 mg	QID	10–14 days
Tetracycline plus	500 mg	QID	10–14 days
PPI	Standard dose[a]	Daily or BID[a]	10–14 days
Or			
H_2RA[e]	Standard dose[e]	BID[e]	4–6 weeks
Sequential Therapy[f]			
PPI	Standard dose[a]	BID[a]	Days 1–10
Amoxicillin	1 g	BID	Days 1–5
Clarithromycin	250–500 mg	BID	Days 6–10
Metronidazole	250–500 mg	BID	Days 6–10
Secondary or Rescue Therapy			
Bismuth subsalicylate[d]	525 mg	QID	10–14 days
Metronidazole	500 mg	QID	10–14 days
Tetracycline	500 mg	QID	10–14 days
PPI	Standard dose[a]	Daily or BID[a]	10–14 days
Or			
PPI	Standard dose[a]	BID[a]	10–14 days
Amoxicillin	1 g	BID	10–14 days
Levofloxacin	500 mg	Daily	10–14 days

[a] Omeprazole 20 mg BID, lansoprazole 30 mg BID, pantoprazole 40 mg BID, rabeprazole 20 mg daily or BID, esomeprazole 20 mg BID or 40 mg daily.

[b] Although 7 to 10 day regimens may provide acceptable eradication rates, the preferred treatment duration in the United States is 14 days.

[c] Use amoxicillin in non–penicillin-allergic individuals; substitute metronidazole for amoxicillin in penicillin-allergic patients.

[d] Pylera, a prepackaged H. pylori regimen, contains bismuth subcitrate potassium (biskalcitrate) 140 mg as the bismuth salt in place of bismuth subsalicylate, metronidazole 125 mg, and tetracycline 125 mg per capsule. The patient is directed to take three capsules per dose with each meal and at bedtime. A standard dose of a PPI is added to the regimen and taken twice daily. All medications are taken for a 10-day period.

[e] See Table 23-1 for standard peptic ulcer healing dosage regimens.

[f] Requires validation in the United States.

BID, 2 times a day; H_2RA, H_2 receptor antagonist; PPI, proton-pump inhibitor; QID, 4 times a day.

• If symptoms continue while on PPI, refer for further evaluation
• If no, perform serology
• If negative, begin treatment with PPI
• If positive, begin treatment with eradication regimen
• If previously treated for *H. pylori*, EGD to determine ulcer status
• Stop NSAID
• Treat ulcer with PPI
• Continue NSAID or switch to more COX-2–selective NSAID
• Treat ulcer with PPI followed by cotherapy with PPI or misoprostool

Figure 23-4 Management of peptic ulcer disease. COX-2, cyclooxygenase-2; EGD, esophagogastroduodenoscopy; GERD, gastroesophageal reflux disease; H. pylori, Helicobacter pylori; NSAID, nonsteroidal anti-inflammatory drug; NUD, non-ulcer dyspepsia; PPI, proton-pump inhibitor.

Drug regimens used to treat and prevent NSAID-induced ulcers are identified in Table 23-1. Patients with NSAID-induced ulcers should be tested to determine their H. pylori status. If the patient is H. pylori negative, the NSAID should be discontinued and treatment should be initiated with antiulcer medications. The duration of treatment should be extended if the NSAID is continued. Prophylactic co-therapy with a PPI or misoprostol or switching to an NSAID with greater COX-2 selectivity is recommended for patients at risk of exhibiting ulcer-related upper GI complications.

HELICOBACTER PYLORI–RELATED PEPTIC ULCER

CASE 23-1

QUESTION 1: R.L. is an otherwise healthy 45-year-old man who works in a high-stress job as an air traffic controller at a major airport. He complains of a 2-week history of "burning stomach pain" sometimes accompanied by "indigestion and bloating." The pain initially occurred several times a day, usually between meals, and sometimes awakened him at night, but it has increased in frequency during the last week. Initially, the pain was temporarily reduced by food or antacids. Last week, R.L. tried an OTC H_2 receptor antagonist that "lasted longer" but did not provide adequate symptom relief. R.L. states that he experienced a similar type of pain about 12 years ago when he was treated with omeprazole for a suspected peptic ulcer. He has smoked one pack of cigarettes daily for the past 20 years, has an occasional glass of red wine with dinner, and usually drinks 4 to 6 cups of caffeinated coffee throughout the day. R.L. takes acetaminophen when needed for occasional headaches and a daily multivitamin but denies the use of any other OTC or prescription medications, including NSAIDs and the previous use of clarithromycin or metronidazole. He denies nausea, vomiting, anorexia, weight loss, and changes in stool consistency or color. A review of other body systems is noncontributory. He has no known food or drug allergies.

Physical examination is normal except for epigastric tenderness on palpation of the upper abdomen. Vital signs include a temperature of 98.8°F, blood pressure of 132/80 mm Hg, and a heart rate of 78 beats/minute. Pertinent laboratory values include the following:

Hgb, 14.0 g/dL
Hct, 44%
Stool guaiac test, negative

All other laboratory values are within normal limits. What signs and symptoms are suggestive of a recurrent peptic ulcer?

The diagnosis of PUD cannot be made based on symptoms alone and requires visualization of the ulcer crater because the symptomology, severity of pain, and timing of the pain (e.g., seasonal, intermittent, or pain free periods lasting from weeks to years) can differ for each patient and encompass a wide variety of complaints. Most patients with PUD present with abdominal pain that is epigastric and often described as burning or gnawing, whereas others complain of abdominal discomfort, fullness, or cramping. Epigastric pain, however, does not necessarily correlate with an ulcer because patients with ulcer-like symptoms may have NUD and asymptomatic patients may have an NSAID-induced ulcer. Heartburn, bloating, and belching may accompany the pain. Ulcer pain typically occurs during the day but can also awaken the patient from sleep (nocturnal pain). In patients with a duodenal ulcer, epigastric pain frequently occurs between meals and is often relieved by food, but this varies from patient to patient. Alternatively, food may precipitate or accentuate pain in patients with a gastric ulcer.

Antacids and antisecretory medications usually provide relief of ulcer pain in most patients. Pain usually diminishes or disappears during treatment, but epigastric pain after healing often suggests an unhealed or recurrent ulcer. Changes in the character of the pain may suggest the presence of complications. Nausea, vomiting, anorexia, and weight loss are more common with gastric ulcer but may also be suggestive of ulcer-related complication.

CASE 23-1, QUESTION 2: R.L. underwent EGD, which revealed a single 0.5-cm ulcer in the duodenal bulb. The ulcer base was clear without evidence of active bleeding. Antral gastritis was biopsy positive for H. pylori. What risk factors may have contributed to ulcer recurrence in this patient?

R.L. indicates that he had a similar type of abdominal pain about 12 years ago, and he was treated with omeprazole for a suspected peptic ulcer. When conventional antiulcer therapy (e.g., PPI) is discontinued after ulcer healing, the ulcer tends to recur. The most important etiologic factors that influence ulcer recurrence are H. pylori infection and NSAID use. It is not known whether R.L. underwent testing for H. pylori 12 years ago. The patient denies the use of OTC and prescription NSAIDs. The long-term use of maintenance therapy (Table 23-1) to maintain remission after initial ulcer healing with a conventional antiulcer medication was standard practice for years and may have been an option for this patient at the time.[96] However, successful eradication of H. pylori (in an H. pylori–positive patient) cures the infection, heals the ulcer, and eliminates the need for long-term maintenance therapy in most patients.[89,96]

Other factors, such as cigarette smoking, psychologic stress, and diet, may have contributed to ulcer recurrence in this patient. There is strong epidemiologic evidence indicating that cigarette smoking is a major risk factor for PUD and that the risk is proportional to the number of cigarettes smoked per day.[87] Several mechanisms have been postulated, including delayed gastric emptying, inhibition of pancreatic bicarbonate secretion, promotion of duodenogastric reflux, reduction in mucosal prostaglandin production, and increased gastric acid secretion. Although cigarette smoking exacerbates PUD, there is insufficient evidence to conclude that it causes a peptic ulcer, but it is hypothesized that smoking or nicotine might provide an environment for H. pylori infection.

R.L. works as an air traffic controller, which is a high-stress job. The importance of psychologic stress and how it affects PUD is complex and multifactorial. Results from controlled trials are conflicting and have failed to demonstrate a cause-and-effect relationship.[87,96] However, the clinical observation of ulcer patients with high-stress jobs and a stressful lifestyle suggest that they are adversely affected.

Caffeine-containing coffee, tea, and cola beverages; constituents in decaffeinated coffee or tea; caffeine-free carbonated beverages; and alcoholic beverages, such as beer and wine, all increase gastric

---

acid secretion, but there is no evidence that they increase the risk for PUD. Certain foods (e.g., spicy) may cause dyspepsia or worsen ulcer symptoms but do not cause peptic ulcers. In high concentrations, alcohol is associated with acute gastric mucosal damage and upper GI bleeding, but there is insufficient evidence to confirm that alcohol causes ulcers.[87] Dietary restrictions and bland diets do not alter the frequency of ulcer recurrence.

CASE 23-1, QUESTION 3: What are the goals of therapy when treating this patient?

The goals of therapy in an H. pylori–positive patient with an active ulcer, a previously documented ulcer, or a history of an ulcer-related complication are to render the patient asymptomatic, heal the ulcer, eradicate the infection, and cure the disease. Treatment should be effective, well-tolerated, easy to comply with, and cost-effective. Drug regimens should have an eradication rate of at least 80% (intention-to-treat, ITT) or 90% (per protocol analysis) and should minimize the potential for antimicrobial resistance.[111] The use of a single drug (antibiotic, bismuth salt, or antiulcer) does not achieve this goal. Two-drug regimens (PPI and amoxicillin or clarithromycin) are not recommended in the United States because of low and variable eradication rates and because of the inclusion of only one antibiotic.

Primary Treatment for Helicobacter pylori Infection

CASE 23-1, QUESTION 4: What factors should be taken into consideration when selecting a first-line eradication regimen? What are the therapeutic options for first-line H. pylori eradication in the United States? Which is the preferred H. pylori eradication regimen for R.L.?

The selection of a first-line H. pylori eradication regimen should be based on proven effectiveness and should take into consideration antibiotic combinations that permit second-line treatment (if necessary) with different antibiotics, treatment duration, the likelihood of antibiotic resistance, and the ability to adhere to the drug regimen. The antibiotics that have been most extensively studied in the United States and found to be effective in various combinations include clarithromycin, amoxicillin, metronidazole, and tetracycline.[87,89,96] A summary of treatments that will be discussed can be found in Table 23-6.

Current treatment guidelines in the United States and Europe recommend two first-line eradication therapies for patients with an H. pylori–positive peptic ulcer: standard PPI-based three-drug regimens or a PPI or H_2RA bismuth-based four-drug regimen (Table 23-6).[89,111] Despite these recommendations, there are recent concerns about the efficacy of these regimens because of declining eradication rates thought to be related to antibiotic resistance, particularly with clarithromycin, and the potential for nonadherence, especially with bismuth quadruple therapy (see Case 23-1, Question 8).[89,112–116] Controversy exists as to whether standard PPI triple therapy, in its present form, should remain as first-line treatment in the United States.[89,112–116] Some clinicians believe that sequential therapy should replace the standard PPI-based three-drug regimens because of superior eradication rates or that the bismuth-based four-drug regimen should be used exclusively as first-line treatment.[112,116] Others believe that more robust clinical trials involving a broader range of patients is needed before sequential therapy replaces the standard PPI three-drug regimens in the United States, and that medication adherence remains problematic with bismuth quadruple therapy.[89,113,114]

The most recommended treatment for H. pylori infection in the United States has been the standard PPI-based three-drug regimen. When combined with a PPI and clarithromycin, the inclusion of amoxicillin or metronidazole provides similar eradication rates.[89] Amoxicillin is usually preferred initially because it is associated with little or no bacterial resistance, has fewer adverse effects, and leaves metronidazole as an option for second-line therapies.[87] However, recent data suggest that eradication rates with traditional PPI triple therapy have been declining during the last decade from greater than 90% to 71% in the United States and down to 60% in Western Europe. Various strategies have been undertaken to enhance eradication rates, including lengthening treatment duration and increasing the antibiotic or antisecretory drug dosages. The recommended duration of treatment in the United States is 14 days, even though international guidelines recommend 7 to 10 days.[89] The superiority of the 14-day regimen over a 7-day or 10-day treatment course has been confirmed and is less likely to be associated with antimicrobial resistance.[89] A treatment duration of less than 7 days is not recommended and is associated with unacceptable eradication rates.[89] Increasing the antibiotic daily dose or extending antibiotic treatment beyond 14 days usually does not improve eradication rates. The PPI may be extended to 28 days if needed for ulcer healing. Twice-daily dosing of the PPI appears to be more effective than a single daily dose.[117] Pretreatment with a PPI before initiating H. pylori eradication does not decrease the rate of eradication.[118]

Bismuth-based quadruple therapy containing a bismuth salt, metronidazole, tetracycline, and either a PPI or H_2RA has been advocated as first-line treatment because it usually yields satisfactory eradication rates despite increased resistance to clarithromycin.[89,116] The complexity of this regimen and the potential for increased side effects often relegates it to preferred second-line status if not previously used. However, eradication rates, tolerability, and medication adherence were reported to be similar to PPI triple therapy when used as first-line treatment, although both regimens yielded eradication rates of less than 80% ITT.[119] Using a PPI instead of an H_2RA permits a shorter duration of treatment (10 days vs.14 days) and may provide increased efficacy in patients with metronidazole-resistant strains of H. pylori.[89] Increasing the duration of quadruple therapy to 1 month does not substantially increase eradication, although the antisecretory drug may be continued for an additional 2 (PPI) or 4 weeks (H_2RA) in patients with an active ulcer.

Small studies, primarily conducted in Italy, found that sequential therapy with a PPI and amoxicillin for 5 days followed by a PPI, clarithromycin, and an imidazole for an additional 5 days achieved eradication rates (>80% ITT). This made a compelling case to switch to sequential therapy as the preferred first-line treatment in the United States.[112–114] A recent meta-analysis of randomized controlled trials looking at previously untreated adults comparing sequential therapy with preexisting or emerging therapies demonstrated that sequential therapy is superior to a 7-day course of the standard PPI-based three-drug regimens containing clarithromycin.[89,112–116,120–122] However, sequential therapy was not superior when compared with standard three-drug regimens for therapy lasting 10 to 14 days.[115] An increased efficacy has also been reported with sequential therapy in patients with clarithromycin-resistant H. pylori strains.[112,120,123] The rationale for sequential therapy is to initially treat the patient with antibiotics that rarely promote resistance (e.g., amoxicillin) to reduce the bacterial load and preexisting resistant organisms, and then to follow with different antibiotics to eradicate the remaining organisms. Although the precise mechanism for the success of sequential therapy is uncertain, the increased efficacy may be related to the number of antibiotics to which the organism is exposed. In addition, sequential therapy is more complex than standard PPI triple therapy because it requires a mid-course change in medications. Lastly, sequential therapy has not been

adequately compared with standard triple therapy containing a PPI–clarithromycin–metronidazole or bismuth-based quadruple therapy in the United States.

The therapeutic options available for the eradication of H. pylori should be carefully considered in each individual patient. The PPI–amoxicillin–clarithromycin regimen is an acceptable first-line management strategy for R.L., because he has not previously received clarithromycin and has no known allergies to penicillin. Posttreatment testing should be considered but may not be necessary if R.L. remains asymptomatic. Although sequential therapy may overcome clarithromycin resistance, it is unclear, at this time, whether it would provide any increased benefit in this patient.

Patient Education

CASE 23-1, QUESTION 5: R.L. is prescribed a 14-day PPI-based three-drug eradication regimen containing amoxicillin and clarithromycin. What instructions would you provide R.L. regarding his medications?

R.L. should be informed of the importance of taking his medications as prescribed to minimize treatment failure and the development of antibiotic resistance. He should be advised that the PPI is an integral part of the three-drug regimen and should be taken twice daily 30 to 60 minutes before breakfast and dinner (see section on Pharmacotherapy of Drugs Used to Treat Acid-Related disorders, Proton-Pump Inhibitors) along with amoxicillin and clarithromycin.

R.L. should also be informed of the most common side effects associated with his treatment regimen. All antibiotics included in the H. pylori eradication regimens are usually associated with mild side effects including nausea, abdominal pain, and diarrhea. C. difficile–associated diarrhea, a serious antibiotic-related complication, occurs occasionally. Oral thrush and vaginal candidiasis (in women) may also occur. Clarithromycin and metronidazole may cause taste disturbances.

R.L., as well as all other patients receiving H. pylori eradication therapy, should be advised of the risk for clinically important drug–drug interactions that may occur with the medications included in their eradication regimen. Special attention should be given to metronidazole and clarithromycin (inhibitors of CYP3A4), as well as to substrates of CYP2C9 (inhibited by metronidazole).[124] Drug–drug interactions may also occur with H_2RAs and PPIs (see section on Pharmacotherapy of Drugs Used to Treat Acid-Related Disorders).

Regimens for the Management of Helicobacter pylori Infection in Patients with Penicillin Allergies

CASE 23-1, QUESTION 6: What would have been the preferred initial H. pylori eradication regimen if R.L. had a documented allergy to penicillin?

There are two first-line treatment options if R.L. had a documented allergy to penicillin. Metronidazole can be substituted for amoxicillin in the PPI-based three-drug regimen, because similar eradication rates are achieved (Table 23-6).[89,125] Bismuth-based quadruple therapy may also be used, because it provides similar eradication rates to the PPI-based three-drug regimens.[89,119]

If R.L.'s medications included metronidazole, tetracycline, or a bismuth salt, he should be provided additional information on these medications. Metronidazole-containing regimens increase the frequency of side effects (especially when the dose is >1 g/day) and may be associated with a disulfiram-like reaction in patients who consume alcohol. Tetracycline may cause photosensitivity and should not be used in children because it may cause tooth discoloration. Bismuth salts may cause darkening of the tongue and stool.

Regimens that substitute levofloxacin for amoxicillin in PPI triple therapy have been used with success, but there are fewer studies to supporting their efficacy.[126] The most common sequential therapy contains amoxicillin and, therefore, is not suitable for a penicillin-allergic patient.

CASE 23-1, QUESTION 7: What drug substitutions are acceptable in the standard PPI-based three-drug and bismuth-based four-drug eradiation regimens?

There are insufficient data to support the substitution of ampicillin for amoxicillin, doxycycline for tetracycline, and azithromycin or erythromycin for clarithromycin. Substitution of clarithromycin 250 to 500 mg 4 times a day for tetracycline in the bismuth-based four-drug regimen (Table 23-6) yields similar results, but substitution of amoxicillin for tetracycline lowers the eradication rate and is not recommended.[87,96]

CASE 23-1, QUESTION 8: What are the most important predictors of H. pylori treatment outcomes, and how may they alter R.L.'s response to treatment?

The two most important factors in predicting H. pylori treatment outcomes are antibiotic resistance and medication adherence.[89,112,113,116] Antibiotic resistance rates are highly variable throughout the United States and the world and thus are difficult to compare.[89,113,116] However, there is evidence that clarithromycin resistance is increasing in North America and Europe and is thought to be the most important reason for the decreasing efficacy of clarithromycin-containing eradication regimens.[89,112,113,116] Because treatment with clarithromycin may increase the likelihood of H. pylori resistance, clinicians should ask about previous macrolide use when deciding upon an eradication regimen.[89]

The clinical importance of metronidazole resistance is unclear, because higher metronidazole doses and the synergistic effect of combining metronidazole with other antibiotics appear to render resistance to metronidazole more relative.[89,113,116,124] Resistance to amoxicillin and tetracycline is uncommon. Levofloxacin is emerging as a component of eradication therapy, but there are recent reports of increasing resistance to fluroquinolones.[112,113,116,124]

Medication adherence decreases with multiple medications, increased frequency of administration, increased duration of treatment, intolerable adverse effects, and costly drug regimens.[89,112] Although most eradication studies report greater than 95% adherence to medications, this high rate must be questioned because it is very difficult to accurately assess the level of compliance in clinical trials where patients take their own medications.[112] Additionally, medication adherence is usually more problematic in clinical practice. A longer treatment duration may contribute to nonadherence, but missed doses in a shorter regimen may also lead to failed eradication. Most bismuth-based four-drug regimens require the patient to take medications 4 times a day and as many as 18 tablets or capsules per day. The complexity of this regimen as well as a mid-treatment change in medications with sequential therapy should be considered when selecting an eradication regimen. Although mild side effects are common with all of the eradication regimens, some patients will experience clinically important effects that lead to discontinuation of a specific drug or of the entire regimen.

Other factors that may contribute to treatment failure include the high bacterial load, the specific H. pylori strain (e.g., CagA), low intragastric pH, and genetic polymorphism (e.g., CYP2C19 polymorphism) when PPIs are used as part of the eradication regimen.[89,113,116,124,127,128] There are limited data to suggest that smoking, alcohol consumption, and diet may negatively affect eradication.

CASE 23-1, QUESTION 9: What parameters should be monitored to determine R.L.'s response to treatment?

Posttreatment testing to confirm eradication is recommended for patients with an H. pylori–related ulcer, persistent dyspeptic symptoms, MALT lymphoma, or early gastric cancer.[89] However, posttreatment testing is neither practical nor cost-effective for all patients with an H. pylori–positive peptic ulcer.[89] When endoscopy follow up is not necessary, the UBT (Table 23-5) is the preferred test to confirm eradication of H. pylori. To avoid confusing bacterial suppression with eradication, the UBT must be delayed at least 4 weeks after the completion of treatment. The term eradication or cure is used when posttreatment tests conducted 4 weeks after the end of treatment do not detect the organism. Antibody tests should be avoided posttreatment, because antibody titers remain elevated for a long period of time (up to 1 year) before they return to the uninfected range after successful eradication.[88,89] If performed posttreatment, only a negative test is considered to be reliable.

Upper endoscopy should only be used to confirm eradication and ulcer healing if indicated (e.g., severe or frequent recurrent symptoms, current or previous ulcer complication), because the procedure is costly and invasive. When endoscopic follow up is necessary, testing to prove eradication includes a biopsy for the rapid urease test and histology (Table 23-5). Ulcer healing can also be confirmed at that time.

In clinical practice, the need for confirmation of ulcer healing and eradication in light of the declining success with the most commonly recommended eradication regimens must be weighed against the need, feasibility, availability, and cost of tests and procedures. Although posttreatment testing to confirm H. pylori eradication is recommended, patients like R.L., who present with an uncomplicated H. pylori–positive ulcer, are usually monitored for symptomatic recurrence 1 to 2 weeks after completion of drug therapy.[89] The absence of symptoms is considered a surrogate marker for successful ulcer healing and eradication. The persistence, or recurrence, of symptoms within 2 weeks after the end of treatment suggests failure of ulcer healing or eradication or an alternative diagnosis such as GERD.

Secondary or Rescue Therapy for Helicobacter pylori Infection

CASE 23-1, QUESTION 10: What other drug regimens can be used if R.L. fails initial eradication therapy with a PPI–amoxicillin–clarithromycin regimen? What regimens can be used when secondary treatment fails?

All initial eradication regimens require that there be an effective second-line treatment. Eradicating H. pylori is more difficult after initial treatment fails, and attempts to eradicate the organism are extremely variable.[89] Second-line regimens should (a) avoid using antibiotics that were used during initial therapy, (b) use antibiotics that have less problems with resistance, (c) use drugs that have a topical effect (e.g., bismuth), and (d) use a 10- to 14-day treatment duration.[89,112,116,129] If R.L. was not successfully eradicated initially with the PPI–amoxicillin–clarithromycin, he should receive second-line therapy with bismuth subsalicylate, metronidazole, tetracycline, and a PPI for 10 to 14 days.[89,112,116,129,130]

Bismuth-based regimens are the most frequently used second-line treatments in the United States when standard PPI-based three-drug regimens fail (Table 23-6).[89] A number of alternatives have been evaluated in small studies utilizing fluoroquinolone, rifabutin (an antibiotic used to treat tuberculosis), or furazolidone (no longer marketed in the United States).[89,112] The results from the levofloxacin-based clinical trials look promising and suggest that these regimens may be an alternative to second-line bismuth quadruple therapy, especially for patients who have no prior use of a fluoroquinolone.[89,112,126,129] However, increasing fluoroquinolone resistance, which appears to be easily acquired, is of concern and may limit the use of these agents for H. pylori eradication.[129] Various rifabutin-based regimens are effective in treating patients with H. pylori strains resistant to clarithromycin or metronidazole.[89,129] Regimens that include rifabutin should be the last option and only used for patients with multiple eradication failures because the drug is very expensive and there are concerns about major hematologic side effects and the possibility of resistance.[129]

NONSTEROIDAL ANTI-INFLAMMATORY DRUG–INDUCED PEPTIC ULCER

CASE 23-2

QUESTION 1: A.D. is a 70-year-old woman who retired from teaching 5 years ago. A few days ago, she noticed black "tarry" stools and was hospitalized for an upper GI bleed most likely secondary to NSAID use. She complains of "feeling tired" and occasionally dizzy for about 1 week. A.D. presents with a 5-year history of osteoarthritis for which she takes naproxen 250 mg in the morning and 500 mg in the evening. When questioned, she denies the use of corticosteroids, bisphosphonates, anticoagulants, clopidogrel, or a selective serotonin reuptake inhibitor (SSRI). She did not have a history of a previous ulcer or related complication. Other medications include hydrochlorothiazide 25 mg daily and lisinopril 20 mg daily for hypertension, self-directed treatment with enteric-coated aspirin 81 mg daily, calcium carbonate, and a multivitamin. A.D. does not use tobacco or drink caffeinated beverages but does have an occasional glass of wine. She denies epigastric pain, nausea, vomiting, anorexia, and weight loss but notes a recent change in stool color. A review of other body systems is noncontributory other than previously indicated. There are no known food or drug allergies.

Physical examination reveals a well-developed weak woman in no acute distress. The abdomen was normal with no pain on palpation. Bowel sounds were normal with no guarding, masses, hepatomegaly, or splenomegaly. The rectum was normal but with guaiac-positive stool. Vital signs include a temperature of 98.9°F, blood pressure of 100/65 mm Hg, and a heart rate of 90 beats/minute. Pertinent laboratory values include the following:

Hgb, 11.0 g/dL
Hct, 35%
Blood urea nitrogen (BUN), 40 mg/dL
Serum creatinine (SCr), 1.5 mg/dL
All other laboratory values are within normal limits.

What factors placed A.D. at increased risk for experiencing an NSAID-induced ulcer and related upper GI bleeding?

Risk factors for NSAID ulcers and related complications are presented in Table 23-3. The use of nonselective NSAIDs (e.g., naproxen) is linked to a threefold to fourfold increase in upper GI complications, and there is a twofold to threefold increase with

---

COX-2 inhibitors when partially and highly selective agents are evaluated as a group (Table 23-4).[101] The risk for upper GI events occur at any dosage, including low doses of OTC NSAIDs,[131] and can occur at any time during treatment.[94–96] A.D.'s self-treatment with cardioprotective dosages (81–325 mg/day) of aspirin in combination with an NSAID (naproxen) increases her risk of upper GI events to a greater extent than the use of either drug alone.[94–96] The use of buffered or enteric-coated aspirin does not confer added protection from ulcer or upper GI complications.[95,103,132] A.D.'s age (70 years) is an independent risk factor for NSAID-induced ulcers, because risk increases with the age of the patient (Table 23-3).[94,95]

The increased incidence in older patients may be explained by age-related changes in gastric mucosal defense. Although A.D. did not have a history of an ulcer or ulcer-related complication before admission, a history of an NSAID-related upper GI event further increases the risk of NSAID-related GI injury.[94–96] Corticosteroids do not increase the ulcer risk when used alone, but the risk is increased twofold in corticosteroid users who are also taking concurrent NSAIDs.[94–96] The risk of upper GI bleeding is markedly increased when NSAIDs are taken with anticoagulants, bisphosphonates, or antiplatelet medications such as clopidogrel.[54,94–96,101] SSRIs independently increase the risk of upper GI bleeding, and although the magnitude of the risk is variable, it is increased in patients taking NSAIDs.[133–135] The pharmacologic mechanism underlying this adverse effect is thought to be related to SSRI inhibition of platelet aggregation, which may interfere with ulcer healing, but it remains unknown if SSRIs have a direct ulcerogenic effect.[133–135] It is uncertain whether H. pylori is a risk factor for NSAID-induced ulcers, but a higher incidence of PUD in H. pylori–positive patients taking NSAIDs suggests an additive effect, which may increase the risk of NSAID-related GI complications.[94–96] A.D.'s multiple risk factors convey an increased risk for an NSAID-related upper GI event (see Case 23-2, Question 4).

CASE 23-2, QUESTION 2: A.D. was admitted for further evaluation and treatment. An EGD revealed two bleeding antral ulcers (0.2 and 0.4 cm) and endoscopic hemostasis was performed. An antral biopsy was reported to be H. pylori negative. All medications were discontinued before endoscopy. Oral oxycodone was instituted after endoscopy at 5 mg every 6 hours when needed to control A.D.'s arthritic pain while she was hospitalized. Consideration was given to decreasing the naproxen dose and switching to acetaminophen, a nonacetylated salicylate, or a partially selective NSAID (Table 23-4) but none of these options were satisfactory for this patient. Treatment was initiated with a continuous infusion of IV pantoprazole for 3 days, and then switched to oral pantoprazole 40 mg twice a day (BID). A.D. was discharged on pantoprazole 40 mg daily and naproxen 250 mg in the morning and 500 mg in the evening. Hydrochlorothiazide, lisinopril, calcium carbonate, and the multivitamin were reinstituted upon discharge from the hospital. Will A.D.'s gastric ulcer heal if she continues to take the naproxen?

The naproxen should be discontinued, if possible, in the presence of an active ulcer.[87,96] If the NSAID was discontinued and A.D.'s treatment was continued with alternative therapy such as oxycodone, a PPI is the preferred treatment to heal the ulcer because it provides a more rapid rate of ulcer healing (4 weeks) and symptom relief than an H_2RA or sucralfate (6–8 weeks).[87,94,96] Because the naproxen was reinstituted at discharge in the presence of an active ulcer, a PPI is the drug of choice, because potent acid suppression is required to heal the ulcer and relieve the symptoms.[87,94,96] The duration of PPI therapy should be extended from 4 weeks to 8 to 12 weeks as continuing the offending NSAID will interfere with ulcer healing.[87,96] Cardiovascular risk and the need for low-dose aspirin must be determined by the patient's primary-care physician or cardiologist, and if not needed, the aspirin should be discontinued. However, low-dose aspirin should be continued after endoscopic hemostasis in patients at cardiovascular risk.[87,136] Clopidogrel should not be substituted for low-dose aspirin in order to reduce GI bleeding.[54,95]

CASE 23-2, QUESTION 3: Which ulcer-healing regimen would be recommended if A.D. was reported to be H. pylori positive?

All patients with NSAID-induced GI events should be tested for H. pylori (Figure 23-4). A PPI-based eradication regimen is recommended in an H. pylori–positive patient with an active ulcer who is also taking an NSAID. One reason for this is that it is not possible to determine whether the H. pylori, the NSAID, or both actually caused the ulcer. If an individual is tested and found to be H. pylori positive, he or she should be offered eradication therapy whether or not there is a documented ulcer. The selection of a specific regimen (Table 23-6) depends on a number of factors, including whether the individual is allergic to penicillin.

Strategies to Reduce the Risk of Nonsteroidal Anti-Inflammatory Drug–Induced Peptic Ulcers

CASE 23-2, QUESTION 4: Three months later, A.D. returned to her gastroenterologist for a follow up EGD, which confirmed that the gastric ulcers were healed. On return to her primary care physician, the pantoprazole was changed to famotidine 20 mg BID, and the patient was advised to discontinue low-dose aspirin. Current medications include naproxen 250 mg in the morning and 500 mg in the evening, hydrochlorothiazide 25 mg daily, lisinopril 20 mg daily, calcium carbonate, and multivitamins. What pharmacological options are available to reduce the risk of an NSAID ulcer now that A.D.'s initial ulcer is healed and she continues to take the naproxen?

Strategies to reduce the risk of NSAID (including aspirin) ulcers and upper GI complications include co-therapy with a PPI or misoprostol; the use of a COX-2 inhibitor; or various combinations of a PPI, misoprostol, and a COX-2 inhibitor.[46,87,94–96,98,104] All PPIs, when used in standard dosages (Table 23-1), are effective for this indication.[95] Standard H_2RA dosages (Table 23-1) should not be recommended as prophylactic co-therapy to reduce the risk of NSAID ulcers because they are not effective in reducing the risk of gastric ulcer, which is the most common ulcer associated with NSAIDs.[95,96] Higher H_2RA dosages (e.g., famotidine/ibuprofen 26.6/800 mg 3 times a day [DUEXIS]) reduce the risk of gastric and duodenal ulcer but are less effective than a PPI.[94,95] Famotidine 20 mg twice daily may be an alternative to a PPI in patients at risk who are taking low-dose aspirin,[137] but comparative trials with PPIs are needed to support the use of standard dose H_2RAs for this indication. There are no studies that have evaluated the use of H_2RAs in reducing the risk of ulcer-related upper GI complications. H_2RAs may be used when necessary to relieve NSAID-related dyspepsia.

Misoprostol reduces the risk of NSAID-induced gastric and duodenal ulcers,[94–96] as well as the risk of upper GI complications in high-risk patients.[136] Initially, the recommended dosage was 200 mcg 4 times a day, but diarrhea and abdominal cramping limited its use. A lower daily dosage of 600 mcg/day should be used because it reduces GI side effects and is comparable in efficacy.[95,96] Dosage reductions to 400 mcg/day or less minimize GI side effects but compromise gastroprotective effects. When used as co-therapy, misoprostol and PPIs have a similar efficacy in preventing gastric ulcer, but PPIs have few side effects.[95,96] A fixed dosage form containing misoprostol 200 mcg and diclofenac (50 mg or 75 mg) is available, but flexibility to individualize dosage is lost.

Two large randomized, placebo-controlled, multicenter, clinical trials compared the GI safety in patients taking COX-2 inhibitors with those taking nonselective and partially selective NSAIDs and reported a reduction of 50% to 60% in upper GI events with the COX-2 inhibitors.[138,139] A 6-month trial (CLASS) of celecoxib in patients who were not taking low-dose aspirin revealed a statistically lower rate of ulcer complications when compared with that of ibuprofen or diclofenac,[139] but evaluation at 1 year found no GI safety advantage among those taking celecoxib.[95] This explains why celecoxib contains the same GI warnings as the nonselective and partially selective NSAIDs (Table 23-4).[140] In addition, a post hoc analysis at 6 months indicated that patients taking celecoxib and concomitant cardioprotective doses of aspirin had a similar rate of upper GI events as those taking either diclofenac or ibuprofen, thus negating the beneficial effects of celecoxib.[139] Low-dose aspirin appears to have similar effects on other COX-2 inhibitors.

A.D. remains at high risk for another NSAID-related complication even though gastric ulcer healing was confirmed, because she continues to take naproxen. Co-therapy with a PPI or misoprostol is preferred for this patient because both are effective in reducing the risk of NSAID-related upper gastrointestinal events. A.D.'s osteoarthritis is well controlled with naproxen, so there is no need to switch her to celecoxib or another more costly NSAID. Combining PPI therapy with misoprostol is not necessary, but some physicians prefer to use combination therapy for older patients with multiple risk factors. Standard H_2RA dosages (e.g., famotidine 20 mg BID) should not be used as prophylactic co-therapy for A.D., because they are not effective in reducing the risk of NSAID-related gastric ulcer. Although higher H_2RA dosages (e.g., famotidine 40 mg BID) reduce the risk of gastric ulcer, they are less effective than a PPI. The famotidine should be discontinued, and prophylaxis should be instituted with a standard dose of a PPI (e.g., pantoprazole 40 mg daily). All PPIs, when used in standard dosages, are effective for this indication, but A.D.'s out-of-pocket cost should be taken into consideration when selecting a PPI.

Cyclooxygenase-2 Inhibitors and Cardiovascular Toxicity

CASE 23-2, QUESTION 5: What is the concern regarding the use of COX-2 inhibitors and the risk for cardiovascular toxicity?

The risk for cardiovascular events in patients taking COX-2 inhibitors increases with a number of factors, including increased COX-2 selectivity, higher dosages, a longer duration of treatment, and preexisting cardiovascular risk.[95,96,140–142] Although ulcers and related GI complications were less likely with rofecoxib than with naproxen in the VIGOR trial, the number of myocardial infarctions and thrombotic strokes were increased with rofecoxib.[138] Similar cardio thrombotic events were observed in other rofecoxib studies of longer duration.[143] In 2004, rofecoxib was withdrawn from the U.S. market and soon thereafter valdecoxib was withdrawn amid concerns about cardiovascular risk.[95]

The cardiovascular safety of celecoxib has been evaluated, but the risk of myocardial infarction and thrombotic stroke is less certain.[95] Although there was no difference in cardiovascular events when celecoxib was compared with diclofenac and ibuprofen in the CLASS trial,[139] cardiovascular events were significantly higher in a clinical trial where patients were taking higher dosages of celecoxib (400 mg twice daily).[144] Celecoxib remains available in the United States, but the underlying cardiovascular risk of the patient must be assessed when considering the use of this drug. The lowest effective celecoxib dose should always be used for the shortest duration of time.[140]

The risk for cardiovascular events is also increased in patients taking nonselective and partially selective NSAIDs, with the possible exception of naproxen.[95,96,145–147] Naproxen is usually the preferred NSAID, especially in patients with increased cardiovascular risk.[95,96 145–147] If possible, NSAIDs and COX-2 inhibitors should be avoided in patients at very high GI and cardiovascular risk.[95] Consideration should be given to using less risky therapeutic options including acetaminophen, tramadol, or narcotics.[148] Thus, the selection of a drug regimen to reduce the risk of NSAID ulcers and GI complications should not only be based on the GI safety of the NSAID or COX-2 inhibitor but must be weighed against the cardiovascular risk for each patient.[95,96,147]

Stratification of Future Risk for Nonsteroidal Anti-Inflammatory Drug–Induced Peptic Ulcers

CASE 23-2, QUESTION 6: How does a COX-2 inhibitor compare with a PPI and a nonselective or partially selective NSAID when used to decrease ulcer risk and related complications? Have any studies evaluated GI safety in patients taking a COX-2 inhibitor plus a PPI?

There have very few randomized controlled trials in H. pylori–negative patients at high risk for NSAID-related complications that compared the combined therapy of celecoxib with a PPI versus a partially selective NSAID with a PPI or celecoxib alone.[95,149,150] Results from these trials suggest that in high-risk, H. pylori–negative patients, combined therapy with a COX-2 inhibitor and PPI may be more efficacious than a partially selective NSAID plus a PPI or celecoxib monotherapy in reducing NSAID-related ulcer complications. Combining a COX-2 inhibitor with a PPI may be considered in very high-risk patients; however, long-term outcomes are unclear given the longest clinical trial follow up was 1 year.[95,149,150]

CASE 23-2, QUESTION 7: What factors should be considered when evaluating management strategies for patients at risk of experiencing an NSAID-induced ulcer? What risk-reduction strategies are considered acceptable for A.D.?

Strategies to reduce the risk of NSAID ulcers and related complications depend on the assessment of upper GI (Table 23-3) and cardiovascular risks. Although there are no universally accepted definitions, the levels of risk can be arbitrarily stratified into low, moderate, and high GI risk and low or high cardiovascular risk.[95,96] High cardiovascular risk implies a physician-recommended requirement for low-dose aspirin to prevent serious cardio thrombotic events.[95] In general, individuals younger than 65 years, and those taking NSAIDs in the short term who do not require low-dose aspirin, are considered to be at low GI and cardiovascular risk and usually do not require GI risk-reduction therapy.[95,96]

Patients at moderate GI risk typically have one to two risk factors that include age older than 65 years; a history of a prior uncomplicated ulcer; treatment with high-dose NSAIDs; or the concurrent use of aspirin (including low-dose), corticosteroids, or anticoagulants (Table 23-3). The recommended risk-reduction strategy in this group is co-therapy with either a PPI or misoprostol, but misoprostol is usually considered a secondary option because of GI adverse events and the need for more frequent daily dosing.[95,96] If the patient requires low-dose aspirin, naproxen is the NSAID of choice. Although a COX-2 inhibitor provides similar gastroprotective effects as a nonselective or partially selective NSAID plus a PPI or misoprostol, the use of COX-2 inhibitors

(including celecoxib) has declined dramatically because they are typically more costly than the NSAID plus PPI and because of concerns related to myocardial infarction and thrombotic events.[95]

Patients at very high GI risk include those with a prior history of an ulcer-related complication or multiple (>2) risk factors.[95,96] If cardiovascular risk is low, alternative therapies such as oxycodone are preferred, but a COX-2 inhibitor plus a PPI or misoprostol may be used.[95] Although it is best to avoid an NSAID if the patient had a complicated ulcer, some physicians will continue the same NSAID that provided the most effective anti-inflammatory effect. This should be done with extreme caution and with maximally effective co-therapy. NSAIDs and COX inhibitors should be avoided in patients at high GI risk and high cardiovascular risk, and alternative therapy should be used.[95,96]

Patients like A.D., who have a history of a recent ulcer and related upper GI bleed, are at high risk for future NSAID-related ulcers and complications and require an effective risk-reduction strategy. Additionally, A.D. has other factors that contribute to her high-risk status, including her age (70 years) and the continued use of a nonselective NSAID (naproxen). Ranitidine should be discontinued immediately, and A.D. should be switched to an evidence-based risk-reduction regimen. If celecoxib is used, the risk of cardiovascular effects must be weighed against the gastroprotective benefits, especially because A.D. has a history of hypertension. If A.D. had renal dysfunction (creatinine clearance <30 mL/minute), NSAIDs and COX-2 inhibitors should be avoided, and the patient should be treated with other analgesics (e.g., tramadol, narcotics), keeping in mind that NSAIDs and COX-2 inhibitors are associated with fluid retention, hypertension, and renal failure. Although switching naproxen to celecoxib plus a PPI or continuing the oxycodone may be preferred by some, the selection of the optimal strategy for a high-risk patient like A.D. is debatable and should take into consideration the risks, benefits, patient preferences, continued analgesic relief, and cost of treatment. Co-therapy with a PPI or misoprostol is an acceptable risk-reduction strategy given A.D.'s GI and cardiovascular risk. Combination therapy of celecoxib and PPI may represent the greatest GI risk reduction and may be considered in this patient.

CASE 23-2, QUESTION 8: What information should be conveyed to A.D. regarding the combined use of OTC aspirin and NSAIDs?

Remind A.D. that her physician has recommended that she discontinue taking the enteric-coated aspirin and that she should not restart it without his/her consent. Explain to A.D. that enteric-coated aspirin may protect against the topical mucosal damage in the stomach and minimize dyspepsia, but the enteric coating does not prevent an ulcer. Even low-dose aspirin (e.g., 81 mg/day) is capable of causing an ulcer, especially when used in conjunction with an NSAID (naproxen). Buffered aspirin may cause less dyspepsia, but buffering does not prevent ulcers. Taking food, milk, or an antacid with aspirin or NSAIDs may minimize dyspepsia but does not prevent an ulcer. Inform A.D. that she should not take OTC NSAIDs in conjunction with her naproxen unless advised to do so by her physician, because combining NSAIDs will increase the risk for ulcers and GI bleeding. Advise A.D. that even though NSAIDs available for self-treatment may have different generic names (e.g., ibuprofen, naproxen) or brand names (e.g., Advil, Aleve), they all belong to the same drug class and have similar side effects.

CASE 23-2, QUESTION 9: A.D.'s physician decides to maintain her on naproxen but changes the famotidine to lansoprazole 30 mg daily. What instructions should you provide A.D. regarding her medications?

A.D. should be advised of the major signs and symptoms of upper GI bleeding and cardiovascular disease and what action should be taken if these signs or symptoms develop. She should be instructed to take the lansoprazole daily 30 to 60 minutes before breakfast and continue taking naproxen twice daily. The importance of adhering to PPI co-therapy must be stressed, especially because A.D. may not have accompanying dyspeptic or ulcer-like symptoms. There is a strong relationship between the level of adherence to gastroprotective medication and the risk for ulcers and serious GI complications in patients like A.D. who are high-risk NSAID users.[151] Older patients, like A.D., who are at risk for osteoporosis and hip fractures and who require long-term PPI therapy should be counseled to take age-related recommended dosages of a calcium salt and vitamin D and have periodic bone density examinations (see section on Pharmacotherapy of Drugs Used to Treat Acid-Related Disorders).

CASE 23-2, QUESTION 10: What parameters should be monitored to determine A.D.'s response to treatment?

High-risk patients like A.D. who continues to take an NSAID should be closely monitored for upper abdominal pain and signs or symptoms associated with bleeding, obstruction, or perforation. The presence of upper abdominal pain or a change in the severity of the pain may suggest an upper GI complication. Every effort should be made to monitor A.D.'s compliance to her PPI regimen because of the strong relationship between nonadherence and the risk of upper GI complications in high-risk NSAID users.

ZOLLINGER–ELLISON SYNDROME

ZES is an uncommon gastric acid hypersecretory disease characterized by severe recurrent peptic ulcers that result from a gastrin-producing tumor (gastrinoma).[130,152] The primary tumor is usually located in the duodenum or pancreas, but other locations (e.g., mesenteric lymph nodes, spleen, stomach, liver) have been described.[130,152] Although most gastrinomas occur sporadically, about 25% occur in association with multiple endocrine neoplasia type 1 (MEN 1), which is an autosomal dominant inherited syndrome.[152] Most gastrinomas are malignant and tend to be slow-growing, but a small number grow and metastasize rapidly to the regional lymph nodes, liver, and bone. Abdominal pain is the most predominant symptom and is usually related to persistent peptic ulcers, which are less responsive to antisecretory therapy. Duodenal ulcers occur most often, but ulcers may also occur in the stomach or jejunum. Diarrhea, which is present in more than half of patients, may precede ulcer symptoms and results from massive gastric acid hypersecretion, which activates pepsinogen and contributes to mucosal damage.[130,152] Steatorrhea may also occur and results from inactivation of pancreatic lipase by low duodenal pH resulting from excessive acid load.[152] This leads to the precipitation of bile acids, which, in turn, reduces micelle formation necessary for fatty acid absorption. Vitamin B_{12} deficiency may develop secondary to malabsorption related to reduced intrinsic factor activity. GERD often occurs and is complicated by esophageal ulcers and strictures. Other symptoms include nausea, vomiting, upper GI bleeding, and weight loss. Upper GI bleeding is related to duodenal ulceration and may be the presenting symptom.

Epidemiology

The incidence of ZES in the United States is 0.1% to 1.0% among patients with duodenal ulcers.[152] The majority of patients are diagnosed between the ages of 30 and 50 years, with men being slightly more affected than women.[152] The morbidity and mortality of ZES have decreased because of improved medical and surgical management.

Pathophysiology

The pathophysiology of ZES is related to a non-β islet cell gastrin-secreting tumor that stimulates the parietal cells of the stomach to hypersecrete gastric acid.[130,152] Large amounts of gastrin are produced by the gastrinoma cells, usually resulting in a profound hypergastrinemia. The gastric parietal cell mass is expanded in response to the trophic effects of hypergastrinemia and causes an increase in basal and stimulated acid output. Hypersecretion of gastric acid results in severe mucosal ulceration, diarrhea, and malabsorption, and is responsible for the signs and symptoms associated with ZES.

Clinical Assessment and Diagnosis

The diagnosis of ZES is established when the fasting serum gastrin is greater than 1,000 pg/mL and the BAO is greater than 15 mEq/hour in patients with an intact stomach (or >5 mEq/hour in the postgastric surgery patient) or when hypergastrinemia is associated with a gastric pH value less than 2.[152] When serum gastrin is between 100 and 1,000 pg/mL and gastric pH is less than 2, a provocative test (secretin or calcium) is recommended to assist in the diagnosis. Imaging techniques are performed to localize the tumor and are useful in evaluating metastatic disease. Upper endoscopy is performed to confirm mucosal ulcerations. The use of PPIs may mask the clinical presentation and complicate the diagnosis.[130]

Treatment

The goal of treatment for ZES is to pharmacologically control gastric acid secretion and to surgically resect the tumor, if possible. The oral PPIs are the drugs of choice for controlling acid secretion because of their potent and prolonged antisecretory effect. Treatment should be initiated with omeprazole 60 mg/day or an equivalent oral dose of lansoprazole, pantoprazole, esomeprazole, or rabeprazole (Table 23-1) and should be titrated to maintain a BAO less than 10 mEq/hour (1 hour before next dose) in uncomplicated patients or less than 5 mEq/hour in patients with complicated disease.[152] Once adequate control of acid secretion has been achieved, the daily PPI dose should be gradually reduced and administered every 8 to 12 hours. In most patients, an omeprazole dose of 60 to 80 mg/day reduces the BAO to target levels. IV PPIs should be reserved for those patients who are not able to take oral medications. H_2RAs are no longer used to treat ZES, even though they were initially proven to be effective (Table 23-1).

Somatostatin analogues are used with varying success to treat gastrinomas, but they are only available parenterally and rarely used as first-line treatment.[152] Octreotide, a synthetic somatostatin analogue, inhibits gastric acid secretion and decreases serum gastrin concentrations, but its subcutaneous route of administration, frequent dosing, and side effect profile (abdominal pain, diarrhea, gallstones, and pain at the injection site) make it less desirable for use in treating ZES. The long-acting depot formation of octreotide acetate for injection suspension can be administered less frequently and may be useful in controlling temporal growth. Patients with metastatic gastrinomas can be treated with chemotherapeutic agents to inhibit tumor growth or may require resection of the tumor. Localization and surgical removal of the gastrinoma should be considered in all patients unless widespread metastases exist.

GASTROESOPHAGEAL REFLUX DISEASE

GERD is a common acid-related GI disorder associated with a wide array of symptoms, the most frequent of which is heartburn and acid regurgitation. Gastroesophageal reflux (GER) is defined as the retrograde passage of gastric contents from the stomach into the esophagus. It is primarily the result of transient relaxation of the LES. When the LES is relaxed, the esophagus is exposed to small amounts of acidic stomach contents. This normal physiologic event occurs many times throughout the day in healthy individuals.[6,153,154] Protective mechanisms, such as esophageal peristalsis and bicarbonate-rich saliva, quickly return the acidic pH to normal. GERD develops when alterations in reflux result in symptoms, mucosal injury, or both.[65] Esophageal injury occurs with continued exposure of the mucosa to gastric acid and results in inflammation that can progress to ulceration (erosive esophagitis).[6,155] Complications associated with long-standing GERD include esophageal strictures, Barrett metaplasia (replacement of normal esophageal squamous epithelium by specialized intestinal-like columnar epithelium), and adenocarcinoma of the esophagus.[7]

Epidemiology

GERD is a chronic disease that affects patients across all age groups with equal distribution between men and women.[7] In the Western world, the prevalence of GERD is estimated to be about 10% to 20%, with lower prevalence in Asian countries. In Western populations, 25% of patients report heartburn monthly, 12% weekly, and 5% describe daily symptoms.[156,157] It has also been estimated that 7% of the U.S. population have complicated GERD associated with erosive esophagitis; however, this finding is difficult to validate, because most patients do not undergo diagnostic esophageal endoscopy.[7] Many patients with erosive esophagitis are asymptomatic on diagnosis, which suggests that symptoms do not correlate with the degree of esophageal injury. Up to 75% of patients who undergo endoscopic procedures as a result of symptoms associated with GERD have normal esophageal findings.[158] These patients are identified as having functional heartburn, nonerosive reflux disease (NERD), or endoscopy-negative reflux disease (ENRD). Other patients with GERD have symptoms that occur outside the esophagus, which are considered atypical or extraesophageal manifestations of GERD. Extraesophageal manifestations may be present with or without accompanying typical symptoms (e.g., heartburn). Extraesophageal manifestations have been estimated to occur in about 80% of patients with at least weekly symptoms of GERD (see section on Extraesophageal Manifestations).[159]

Childhood GERD appears to continue into adolescence and adulthood. Although most infants exhibit physiologic regurgitation, or spitting up, the majority (95%) will have abatement of symptoms by 1 year of age.[160] However, infants with persisting symptoms beyond 2 years of age are at risk of exhibiting complicated GERD.[161,162] One prospective study evaluated children with a prior diagnosis of complicated GERD (erosive esophagitis) made at approximately 5 years of age, and then reevaluated them 15 years later. This study revealed that 80% of the children reported monthly symptoms of heartburn and regurgitation, and 23% described weekly symptoms. In addition, 30% still required antisecretory therapy, and 24% underwent antireflux surgery[163] (see Chapter 104, Common Pediatric Illnesses). Pregnancy has also been associated with an increased incidence of GERD, with 30% to 50% of pregnant women complaining of heartburn, especially in the second and third trimesters; however, in individuals without a previous diagnosis of GERD, the symptoms resolve when the child is born.[6] The mechanisms for GERD in pregnancy are related to the hormonal effects of progesterone and estrogen, which lower LES pressure, and increase intra-abdominal pressure[6,164] (see Chapter 49, Obstetric Drug Therapy, for complete discussion related to the management as well as the risks and benefits associated with treating GERD in the pregnant patient).

Complications associated with GERD include esophageal erosions (5%), strictures (4%–20%), and Barrett metaplasia (8%–20%).[6] Male sex and advancing age (men and women) are associated with an increase in the prevalence of esophageal complications, presumably as a result of refluxed acidic contents damaging the mucosa over time.[6] When comparing quality of life in patients with GERD to those with other chronic medical diseases, the quality of life in GERD patients was between patients with psychiatric disorders and patients with mild heart failure.[165]

Etiology and Risk Factors

The causes of GERD are associated with factors that increase the frequency or duration of GER leading to increased contact of the acidic refluxate with the esophageal mucosa. Risk factors associated with GERD include dietary and lifestyle factors, drugs, and certain medical and surgical conditions[7,8,153–155,166,167] (Table 23-7). These factors may precipitate or worsen GERD symptoms by lowering the LES pressure (e.g., nitrates, progesterone, foods high in fat, mint, chocolate) or having a direct irritating effect on the esophageal mucosa (e.g., citrus, tomatoes, bisphosphonates). Stress reflux from increased intra-abdominal pressure has been associated with overeating, coughing, and bending or straining to lift heavy objects, as well as tight-fitting clothing.[6,8] Certain medical and surgical conditions, such as gastroparesis, scleroderma, ZES, and long-term placement of nasogastric tubes, may also be associated with GERD.[6]

Table 23-7

Risk Factors Associated With Gastroesophageal Reflux Disease[6,8,153–155,166,167]

Drugs	Dietary
α-Adrenergic agonists	Foods high in fat
Anticholinergics	Spicy foods
Aspirin	Carminatives (peppermint, spearmint)
Barbiturates	Chocolate
Benzodiazepines	Caffeine (coffee, tea, colas)
b_2-Adrenergic agonists	Garlic or onions
Bisphosphonates	Citrus fruits and juices
Calcium-channel blockers	Tomatoes and juice
Dopamine	Carbonated beverages
Estrogen	
Isoproterenol	**Lifestyle**
Iron	Cigarette/cigar smoke
Narcotics	Obesity
Nitrates	Supine body position
NSAIDs	Tight-fitting clothing
Progesterone	Heavy exercise
Potassium	
Prostaglandins	**Medical/Surgical Conditions**
Quinidine	Pregnancy
Tetracycline	Scleroderma
Theophylline	ZES
Tricyclic antidepressants	Gastroparesis
Zidovudine	Nasogastric tube intubation

NSAID, nonsteroidal anti-inflammatory drug; ZES, Zollinger–Ellison syndrome.

Pathophysiology

The pathophysiology of GERD is associated with defects in transient relaxations of the LES, esophageal acid clearance and buffering capabilities, anatomy, gastric emptying, mucosal resistance and with exposure of the esophageal mucosa to aggressive factors (gastric acid, pepsin, and bile salts) leading to esophageal damage.

TRANSIENT RELAXATIONS OF THE LOWER ESOPHAGEAL SPHINCTER

The LES, when in a resting state, remains at a high pressure (10–30 mm Hg) to prevent the gastric contents from entering into the esophagus.[6] Pressures are lowest during the day and with meals and highest at night.[6] Transient relaxations of the LES are short periods of sphincter relaxation that are different from those that occur with swallowing or peristalsis.[7,168,169] They occur as a result of vagal stimulation in response to gastric distension from meals (most common), gas, stress, vomiting, or coughing and can persist for more than 10 seconds.[7] These transient relaxations of the LES are associated with virtually all GER events in healthy individuals but account for 50% to 80% of occurrences in patients with pathogenic GERD.[7] Thus, not all transient relaxations of the LES are associated with GERD.

A small percentage of patients may also have a continuously weak and hypotensive LES (decreased LES resting tone). Stress reflux increases intra-abdominal pressure and may blow open the hypotensive LES.[7] When LES pressures remain constantly low, the risk for serious complications (e.g., erosive esophagitis) increases dramatically. Scleroderma, which is related to fibrosis of smooth muscle, may reduce LES tone and increase the potential for GERD.[170]

ESOPHAGEAL ACID CLEARANCE AND BUFFERING CAPABILITIES

Although the number of reflux events and quantity of refluxate are notable, it is the duration of time the mucosa is in contact with these noxious substances that determines esophageal damage and complications. More than 50% of patients diagnosed with severe esophagitis have decreased acid clearance from the esophagus.[6] Peristalsis is the primary mechanism by which acid refluxate is removed from the esophagus. Other mechanisms include swallowing, esophageal distension in response to refluxate, and gravity (which is only effective when the patient is in an upright position).

Saliva plays an important role in the neutralization of gastric acid within the esophagus. Its bicarbonate-rich content buffers the residual acid that remains in the esophagus after peristalsis.[6] However, saliva is only effective on small amounts of gastric acid, because patients with larger volumes of acid refluxate may not have the neutralizing capacity in saliva necessary to protect the esophagus.[6] Swallowing increases the rate of saliva production and esophageal acid clearance. The reduction of swallowing that occurs during sleep is associated with nocturnal GERD. Patients with decreased saliva production (e.g., elderly, patients taking medication with anticholinergic effects, and those with certain medical conditions such as xerostomia or Sjögren syndrome) may also be at increased risk of experiencing GERD.[6,171]

ANATOMIC ABNORMALITIES

Hiatal hernia (protrusion of the upper portion of the stomach into the thoracic cavity because of weakening in the diaphragmatic muscles) is frequently described as a cause of GERD, but its causal relationship remains uncertain.[6] Although hiatal hernia is associated with a greater degree of esophagitis, strictures, and Barrett metaplasia, not all patients with hiatal hernia exhibit symptoms or complications. This may be related to the size of the hiatal hernia and its effect on LES pressure.[6] An increase in the size of the hernia may decrease its ability to remain below the diaphragm during swallowing, and thus, reduces LES pressure. Hypotensive LES in combination with hiatal hernia increases the likelihood of reflux and complicated disease.[6]

GASTRIC EMPTYING

Delayed gastric emptying increases the volume of gastric fluid remaining within the stomach that is available for reflux and is associated with gastric distension.[6] Although delayed gastric emptying is present in up to 15% of patients with GERD, a causal relationship has not been established.[6,172] Because some patients, such as those with diabetic gastroparesis, also have GERD, the association between delayed gastric emptying and GERD cannot be overlooked.[6]

MUCOSAL RESISTANCE

The capability of the esophageal mucosa to endure contact with and withstand injury from gastric refluxate (acid and pepsin) is a substantial determinate for the development of GERD. When considering the mucosal resistance within the esophagus compared with that of the stomach and duodenum, the esophagus is less resistant to damage from gastric acid.[6] However, mucosal resistance in the esophagus is composed of many defensive factors working in tandem to prevent esophageal injury. An increase in mucosal cell thickness and intracellular junctional complexes prevents the diffusion of hydrogen ions from penetrating into the esophageal epithelium and leading to cell death.[6] The esophagus also secretes a protective mucous layer and bicarbonate.[6,173] Enhanced blood flow in response to an acidic environment within the esophagus improves tissue oxygenation, provides nutrients, and helps to maintain a normal acid–base balance.[6] Esophageal injury also occurs when the concentration of acid and pepsin exceed the protection afforded by mucosal resistance mechanisms.

AGGRESSIVE FACTORS ASSOCIATED WITH ESOPHAGEAL DAMAGE

The gastric refluxate, which is composed primarily of gastric acid and pepsin, is the primary aggressive factor associated with GERD. The development and degree of mucosal damage is dependent on the pH and contents of the refluxate as well as the total exposure time of refluxate with the esophageal mucosa. A pH less than 4 is usually required to produce injury to the esophageal mucosa, but as the refluxate becomes more acidic, the mucosal damage is accelerated.[6] The addition of pepsin (which is converted from secreted pepsinogen in an acidic pH) to the acidic refluxate will markedly increase the propensity of the refluxate to compromise mucosal resistance and increases the potential for esophageal bleeding.[6,172,174] Duodenogastric reflux or alkaline reflux containing bile acids and pancreatic juices may also contribute to esophagitis.[6] Because gastric and duodenogastric reflux are often concomitantly present, their actions may be additive in causing esophageal damage.

The duration of total exposure time of the esophagus to the refluxate is the primary mechanism involved in the development of GERD and its complications. The longer the duration of exposure time, the greater the possibility of severe disease, including progression to Barrett metaplasia.

ERADICATION OF HELICOBACTER PYLORI

The relationship between H. pylori infection and GERD remains controversial.[175] Conflicting data from earlier studies suggested that H. pylori eradication is associated with increase gastric acidity and development of erosive esophagitis; however, this observation is not supported by the current treatment guidelines for H. pylori infection. Routine H. pylori testing in patients with GERD is not standard practice, if the patient is tested and found to be H. pylori positive, eradication is recommended[89] (see section on Primary Treatment for Helicobacter pylori).

Clinical Presentation

SIGNS AND SYMPTOMS

CASE 23-3

QUESTION 1: W.J. is a 39-year-old, 130-kg, 170-cm-tall man who presents with complaints of indigestion. He describes a burning sensation behind his breastbone and some belching that is often associated with an acid taste in the back of his mouth. He indicates that his symptoms began a few months ago, and they only occur a few times a month, especially after eating large or spicy meals. Also, if he eats too close to bedtime, the burning keeps him up at night. He has used liquid antacids in the past for these symptoms and states they work fairly well, but he has to take frequent doses, because the symptoms return quickly. He does not take any other medications. Which of W.J.'s symptoms are consistent with GERD?

Symptoms that are typically associated with GERD include heartburn, pyrosis (a retrosternal burning that occurs in the upper esophagus and travels up through the throat), regurgitation of gastric contents into the throat, or in many patients, the presence of both.[6,65,171] These symptoms may be episodic or meal related and are often alleviated by antacids.[6] Heartburn, the most frequent typical symptom, is caused by the contact of acidic refluxate with nerve endings within esophageal mucosa.[6] Other symptoms include water brash (salty or sour fluid occurring abruptly within the mouth), early satiety, belching, hiccups, nausea, and vomiting.[6] Worrisome symptoms (alarm signs or symptoms) include dysphagia (trouble swallowing), odynophagia (painful swallowing), vomiting of blood, bloody or tarry stools, unexplained weight loss, and anemia.[6,65] These symptoms suggest complicated disease, such as erosive esophagitis, esophageal stricture, malignancy, or GI bleeding, and require immediate evaluation by a health-care professional. Some patients, such as the elderly, may not have typical GERD symptoms but present initially with alarm symptoms.[6,176] This is attributable in part to older patients having a reduced pain perception and a possible reduction in the acidity of the refluxate.[6] Other patients may present with only extraesophageal or atypical symptoms (see section on Treatment for the Extraesophageal Manifestations of Gastroesophageal Reflux Disease). Despite the lack of esophageal symptoms, the potential for serious esophageal damage exists, because there is no correlation between symptoms and the degree of esophageal injury.[6] W.J.'s symptoms of a burning sensation (heartburn), regurgitation soon after eating spicy or large meals, and the association of symptoms with eating a meal near his bedtime are all consistent with GERD. The fact that his symptoms are relieved by his use of antacids is also suggestive of GERD.

Treatment

THERAPEUTIC GOALS

CASE 23-3, QUESTION 2: What are the therapeutic goals for the treatment of W.J.'s GERD?

The therapeutic goals for the management of GERD are to alleviate symptoms, promote esophageal healing, prevent recurrence, provide cost-effective pharmacotherapy, and avoid long-term complications.[6] One long-term consequence is Barrett esophagus, or Barrett metaplasia, which is identified in 10% to 15% of GERD patients on endoscopic evaluation.[6,177] This premalignant condition may predispose the patient to esophageal adenocarcinoma. Patients with Barrett esophagus have a risk of exhibiting esophageal cancer that is 30 to 40 times higher than patients without this disorder.[177] GERD is a chronic disease that carries the potential for serious complications.

NONPHARMACOLOGIC MEASURES AND SELF-DIRECTED TREATMENT

CASE 23-3, QUESTION 3: What lifestyle and dietary changes may potentially reduce W.J.'s GERD symptoms?

Lifestyle and dietary modifications comprise the initial step in managing patients with GERD[8,65,167,175,178] (Table 23-8). Strategies should be discussed with the patient and tailored to his or her specific needs. The paucity of evidence to date suggests that although many patients may benefit from these modifications, they are unlikely to completely alleviate symptoms in most patients.[65,171,178] Lifestyle modifications are aimed at reducing acid exposure within the esophagus by increasing LES pressure, decreasing intragastric pressure, improving esophageal acid clearance, and avoiding specific agents that irritate the esophageal mucosa. There is evidence to support several modifications that reduce esophageal gastric acid exposure and symptoms.[65,178] These include raising the head of the bed 6 to 8 inches by using blocks underneath the legs of the bed or using a foam wedge instead of traditional pillows; sleeping in a left lateral decubitus position; and weight loss, which also decreases intragastric pressure.[65,178]

Patients with GERD symptoms should avoid foods and beverages known to trigger symptoms (Table 23-7). However, the evidence suggesting benefit remains uncertain.[65,178] However, individualized lifestyle and dietary modifications should be recommended to all patients with GERD symptoms. When appropriate, OTC or prescription medications should be recommended.[8]

W.J. should be counseled to lose weight, wear loose-fitting clothing, and avoid eating spicy meals that he knows will exacerbate his symptoms. Recommend that he avoids eating at least 3 hours before bedtime as this may help decrease symptoms and consider raising the head of his bed 6 to 8 inches with wooden blocks.

CASE 23-3, QUESTION 4: Which OTC treatment options (if any) would you recommend for W.J.?

Many patients with mild, infrequent symptoms can be managed with OTC medications[6,8,179–181] (Fig. 23-5). First, a determination must be made as to the suitability of the patient for self-treatment. If the patient does not meet the criteria for self-treatment as described subsequently, he or she should be referred for further medical evaluation.[6,8,180,181] It is important to ensure that the following are not present: alarm signs or symptoms, severe or frequent (2 or more days a week) heartburn lasting greater than 3 months, presence of extraesophageal manifestations (see Case 23-5), or symptoms that persist despite appropriate drug therapy. OTC antacids and H_2RAs are the drugs of choice for patients with mild, infrequent heartburn. The nonprescription PPIs (omeprazole, immediate-release omeprazole with sodium bicarbonate, and lansoprazole) should be reserved for patients who experience frequent heartburn.[8]

Antacids remain an effective option for treating mild, infrequent heartburn, because they rapidly (within minutes) relieve symptoms, but the duration of symptom relief only lasts about 30 minutes when taken on an empty stomach.[7,8,180] The duration can be extended for several hours if taken within 1 hour after a meal.[8] Antacids are available in tablet and liquid form and are usually interchangeable when used in recommended dosages.[8] The dose can be repeated every 1 to 2 hours as needed, but the maximum recommended daily dose should not be exceeded. The addition of alginic acid to the antacid may improve symptom relief for some patients.[8,179] Patients requiring frequent or regular antacid use for more than 2 weeks should be reevaluated, because an OTC H_2RA or PPI may be needed.[8,180,181] About 20% of patients will achieve symptom relief with the use of antacids.[6] Antacids are not effective in healing erosive esophagitis.[7]

The OTC H_2RAs are indicated for mild to moderate infrequent GERD symptoms.[8,180] When compared with antacids, their onset of symptom relief occurs within 30 to 45 minutes, and they have a longer duration of action (up to 10 hours).[6,8] One benefit of the H_2RAs is that they can be taken before eating a heavy or spicy meal as prophylaxis for postprandial GERD symptoms.[6,8] They also have a beneficial effect on reducing nocturnal acid secretion.[8] Tachyphylaxis (tolerance) has been reported with continued use of H_2RAs, but this effect can be overcome with intermittent or as-needed use.[8] OTC H_2RAs are available in one-half the original prescription low dose and as full prescription doses. Patients should use the lower OTC dose twice daily for mild, intermittent symptoms and the higher dose twice daily for moderate symptoms[8] (Table 23-1). The four OTC H_2RAs (cimetidine, famotidine, ranitidine, nizatidine) are interchangeable when used in recommended dosages.[8] Patients should avoid cimetidine if the potential for a clinically important drug interaction exists with drugs metabolized by the hepatic CYP450 enzyme system. When used for self-treatment, the H_2RA dose should not exceed two doses per day, and the treatment duration should not exceed 2 weeks. Use beyond 2 weeks should be under the care of a health-care provider.[6,8]

Table 23-8

Dietary and Lifestyle Modifications Used to Manage Gastroesophageal Reflux Symptoms[8,65,167,178]

Dietary	Medication	Lifestyle
Avoid foods listed in Table 23-7	Avoid medications with a potential to relax the lower esophageal sphincter or that have a direct irritant effect on the esophageal mucosa (Table 23-7)	Stop or decrease smoking/tobacco
Avoid eating large meals	Medications with the potential to irritate the esophagus should be taken with a full glass of water	Avoid alcohol
Avoid eating within 3 hours of bedtime		Lose weight[a]
		Elevate the head of bed 6–8 inches or use a foam wedge[a]
		Sleep in the left lateral decubitus position[a]

[a] Sufficient evidence exists to support lifestyle modification.

Maintenance therapy

Figure 23-5 Management of GERD. GERD, gastroesophageal reflux disease; H_2RA, H_2 receptor antagonist; PPI, proton-pump inhibitor.

Esomeprazole, lansoprazole, and omeprazole are PPIs available OTC and are potent inhibitors of gastric acid and are indicated for use in patients with frequent heartburn (2 or more days a week).[8] The onset of symptom relief is slower (2–3 hours) than with H_2RAs, and complete relief may require up to 4 days after initiating therapy. PPIs are superior to H_2RAs with regard to symptom relief and duration of acid suppression.[8] Patients should take the OTC PPIs 30 to 60 minutes before a meal (breakfast is preferable) and not take more than one dose daily for up to 2 weeks. Another course of therapy should not be taken more than every 4 months unless directed by a health-care provider, because this may indicate more serious disease.[6,8,180,181]

W.J. is an appropriate candidate for self-treatment because his symptoms are mild and occur infrequently, and he has no alarm symptoms. Although antacids are an acceptable option for W.J., he has tried these and is unhappy with the frequency of dosing needed to relieve his heartburn. Because W.J. has requested a medication to specifically "prevent" meal-related symptoms, he should take an H_2RA 30 to 60 minutes before eating or drinking. If symptoms remain infrequent but are unrelated to meals, the use of an OTC H_2RA as needed for symptoms may be required. He can increase the dose to twice daily if symptom relief is not optimal and may consider an OTC PPI if symptoms occur more than 2 days a week. If he continues to have symptoms beyond 2 weeks, they become more severe, or they are accompanied by alarm symptoms, he should be referred for further evaluation.

SEVERE DISEASE WITH COMPLICATIONS

CASE 23-4

QUESTION 1: L.F. is a 48-year-old woman who presents to her primary-care provider complaining of recurrent heartburn occurring daily for the past 6 weeks. She states that the heartburn occurs frequently after meals and often wakens her at night. Lately, she has been experiencing difficulty swallowing solid foods. L.F. currently smokes two packs of cigarettes per day and likes to have two glasses of wine each night with her dinner. She states that she occasionally uses OTC ranitidine 150 mg orally up to twice daily, which temporarily relieves her symptoms. What diagnostic modalities are available for the evaluation of her GERD?

Clinical Assessment and Diagnosis

Numerous diagnostic options exist for the evaluation of the patient with presumed GERD. The medical history should include the identification of specific symptoms and an assessment of symptom frequency, severity, and duration as well as risk factors or triggers. An empiric diagnosis can be made in the majority of patients based on the symptoms of heartburn and regurgitation. However, patients who present with severe symptoms, alarm symptoms, or long-standing GERD or who do not respond to empiric therapy warrant further diagnostic evaluation.

ACID SUPPRESSION EMPIRIC TEST

A trial of a PPI is commonly used to empirically diagnose typical GERD-like symptoms in patients without alarm symptoms or symptoms of complicated disease. Doses used in clinical trials range from 20 to 80 mg of omeprazole (or equivalent) once daily for up to 4 weeks.[6,182] If symptoms are relieved after a short trial of a PPI (7 to 14 days), an empiric diagnosis of GERD may be made and other invasive and costly diagnostic methods may be avoided.[6,153,179,182,183] However, this methodology is not without its limitations. The test cannot differentiate between other acid-related disorders, such as PUD, and studies evaluating its ability to detect GERD versus other diagnostic options have been equivocal.[6,182,183] Despite these shortcomings, guidelines suggest that an empiric trial of a PPI is appropriate in selected patients given its ease of use and reduced cost.[65] The empiric use of a PPI may also be beneficial in

---

identifying patients with extraesophageal manifestations of GERD[6] (see section on Treatment for Extraesophageal Manifestations of Gastroesophageal Reflux Disease). Further diagnostic evaluation is warranted in patients who do not respond to acid suppressive therapy, who present with alarm symptoms or symptoms suggestive of complicated disease, or who have long-standing GERD where the possibility of

Barrett esophagus exists.

UPPER ENDOSCOPY AND BIOPSY

Upper endoscopy is the primary diagnostic method for evaluating the esophageal mucosa for injury or cellular changes. (To view a video of severe esophagitis, go to http://www.gastrointestinalatlas.com/english/esophagitis.html.) This test is highly specific, yet only moderately sensitive for the diagnosis of GERD, because many patients present with nonerosive disease. There are four primary reasons why endoscopy is performed in patients suspected of having GERD[6,184]: (a) to rule out significant disease (e.g., adenocarcinoma of the esophagus) or complications (e.g., stricture); (b) to screen for Barrett metaplasia; (c) to evaluate and grade the severity of esophagitis; and (d) to allow the provider to optimize treatment and predict the long-term course of the disease. The endoscope can be fitted with surgical instruments to allow the operator to perform procedures or obtain tissue specimens for biopsy. Endoscopic grading of the esophagus is based on the level of inflammation and mucosal damage. Two endoscopic classification systems are used for the grading of esophagitis[185,186] (Table 23-9). The Savary–Miller classification categorizes patients from grade 0 to grade 4 based on the severity of mucosal erosions of the esophagus.[185] The addition of a grade 5 was added to include the diagnosis of Barrett esophagus.[187] Although this classification system is no longer recommended in the United States, it is still used in many practices, as well as in Europe. The Los Angeles classification is preferred because it is more specific and categorizes patients from grades A to D based on the number of mucosal breaks, their size, and the amount of surface area with esophagitis involvement.[186] There is no classification for normal esophagus with this system and symptomatic patients are often classified with NERD.

Biopsy of the esophageal mucosa is performed during endoscopy, and tissue samples are evaluated by microscopy for evidence of Barrett metaplasia or neoplastic disease.[8] In patients with suspected Barrett metaplasia, the biopsy is obtained after the esophagus has healed to prevent misinterpretation of the inflammatory markers for dysplastic syndrome. Mucosal biopsy for inflammatory markers in nonerosive disease remains debatable.

TWENTY-FOUR–HOUR CONTINUOUS AMBULATORY pH MONITORING

Ambulatory pH monitoring is a valuable diagnostic test for evaluating GERD. It is especially helpful in patients who have not responded adequately to reasonable pharmacotherapy, in patients with nonerosive disease, and when there is a need to correlate reflux events with symptoms. A small (2–3 mm diameter) pH electrode is threaded through the patient’s nostril (similar to placing a nasogastric tube), past the patient’s larynx, to approximately 5 cm above the LES in the distal esophagus.[6] Once it is connected to a logging device, which documents pH measurements every few seconds, it allows for the determination of reflux events (defined as esophageal pH

<4), duration of reflux events, and percentage of time within a 24-hour period that the patient's pH is less than 4. The patient is asked to keep a diary to record symptomatic events that can be correlated with a decrease in esophageal pH. This is especially important when correlating extraesophageal manifestations with reflux events.

RADIOLOGIC TESTING

The barium esophagram (barium swallow) is used primarily to identify suspected esophageal abnormalities, such as strictures, narrowing, and hiatal hernia, and to determine peristalsis disorders.[6] The procedure is relatively noninvasive and inexpensive when compared with endoscopy.

ESOPHAGEAL MANOMETRY

Esophageal manometry is used to evaluate the patient's LES pressure and esophageal peristalsis.[7] This procedure does not have a specific role in the diagnosis of GERD, because it does not detect the presence of acid within the esophagus. It is used primarily to evaluate patients before 24-hour continuous ambulatory pH monitoring and antireflux surgical procedures (e.g., Nissen fundoplication) to determine the location of the LES.[7,188]

CASE 23-4, QUESTION 2: L.F.'s frequent severe symptoms continue despite OTC ranitidine 150 mg orally twice daily, and the presence of warning signs warranted that she undergo endoscopy, which revealed moderate esophagitis (Los Angeles grade C), the presence of an esophageal stricture, and no evidence of Barrett metaplasia. Esophageal dilation was performed during the procedure to widen the lumen of the esophagus. What treatment options exist for L.F.?

Table 23-9

Classification Systems for Endoscopically Determined Esophagitis[185–187]

The Savary–Miller Classification System of Esophagitis	
Grade 0	Normal esophageal mucosa
Grade 1	Erythema or diffusely red mucosa, edema causing accentuated folds
Grade 2	Isolated round or linear erosions extending from the gastroesophageal junction upward, not involving entire circumference
Grade 3	Confluent erosions extending around entire circumference or superficial ulceration without erosions
Grade 4	Complicated cases; erosions as in grade 3 plus deep ulcerations, strictures, or columnar epithelium-lined esophagus
Grade 5	Presence of Barrett metaplasia
The Los Angeles Classification System of Esophagitis	
Grade A	One (or more) mucosal break no longer than 5 mm that does not extend between the tops of two mucosal folds
Grade B	One (or more) mucosal break more than 5 mm long that does not extend between the tops of two mucosal folds
Grade C	One (or more) mucosal break that is continuous between the tops of two or more mucosal folds but

	that involves <75% of the circumference
Grade D	One (or more) mucosal break that involves at least 75% of the esophageal circumference

---

Pharmacotherapy

ANTACIDS

Antacids are useful only in the relief of mild symptoms associated with GERD (see section on Nonpharmacologic Measures and Self-directed Treatment). Because of their short duration of action and inability to heal erosive esophagitis, they are not an option for treating moderate to severe GERD.[6,8]

HISTAMINE-2 RECEPTOR ANTAGONISTS

H_2RAs are effective in treating patients with mild to moderate GERD, but response rates vary with the severity of disease, the dose of the drug, and the duration of therapy. H_2RAs are considered equally effective when used in equipotent doses for symptomatic relief and esophageal healing (Table 23-1). They are effective in reducing nocturnal symptoms but only modestly effective in relieving meal-related symptoms, because they only block one mechanism of parietal cell activation (the H_2 receptor).[6] H_2RAs relieve symptoms in about 50% to 60% of patients treated after 12 weeks of continuous therapy and are superior to placebo.,[189] Increasing the H_2RA dose may not improve symptoms in some patients.[190] Esophageal healing requires higher doses (e.g., famotidine 40 mg BID) compared with those used for symptom relief (Table 23-1). Esophageal healing rates with H_2RAs are reported to be about 50% after 8 to 12 weeks of treatment, but rates will vary depending on the degree of esophagitis.[189] For example, endoscopic healing rates in trials with high-dose H_2RAs were approximately 60% to 90% in patients with grades 1 and 2 esophagitis but were only 30% to 50% in patients with more severe disease (grades 3 and 4 esophagitis).[6,189] Some investigators have attributed inadequate esophageal healing to the development of tachyphylaxis.[179]

PROTON-PUMP INHIBITORS

PPIs are the drugs of choice for patients with frequent moderate to severe GERD symptoms and esophagitis because they provide more rapid relief of symptoms and esophageal healing than do H_2RAs. When used in recommended dosages, all of the PPIs provide similar rates of symptom relief and esophageal healing (Table 23-1). Their superior efficacy, when compared with H_2RAs, is related to their ability to maintain an intragastric pH less than 4 for a long duration time (up to 24 hours/day vs. up to 10 hours with a H_2RA).[8,191] Typically, PPIs are taken once daily 30 to 60 minutes before breakfast, but if a second dose is required, it should be taken before the evening meal.

A large meta-analysis of 16 trials confirms that PPIs are superior to H_2RAs for achieving rapid and complete relief of GERD symptoms. Complete symptom relief (within 4–12 weeks) was achieved in 77.4% of patients taking a PPI versus 47.6% of those taking an H_2RA ($p < 0.0001$).[189] PPIs have also been shown to heal esophagitis more quickly and effectively than H_2RAs. In the same meta-analysis, which evaluated 43 double-blinded or single-blinded, randomized studies (including patients with severe esophagitis), PPIs (83.6%) were more effective than H_2RAs (51.9%) at healing erosive esophagitis at 12 weeks.[189] Healing also occurred more quickly with PPI therapy in that by week 2, 63.4% of patients had healed with the PPI, whereas it took 12 weeks with the H_2RAs for 60.2% of patients to heal.[189] Another large meta-analysis, which evaluated more than 33 randomized trials, demonstrated similar results with 81.7% of patients healed at 8 weeks with a PPI versus 52.0% with an H_2RA.[42]

Esophageal healing among PPIs appears to be equivalent, because about 85% to 90% of patients achieve complete healing at 8 weeks in numerous head-to-head trials with equivalent doses.[37–40] One meta-analysis, which compared esophageal healing rates among omeprazole 20 mg, lansoprazole 30 mg, pantoprazole 40 mg, and rabeprazole 20 mg (each given once daily), reported no statistical difference.[36] However, all of the PPIs were superior to ranitidine 300 to 600 mg/day. Esomeprazole 40 mg once daily has been reported to be superior to omeprazole 20 mg once daily, at both 4 and 8 weeks, when used to heal erosive esophagitis.[192] However, the esomeprazole 40 mg and omeprazole 20 mg dosages are not equipotent, and this study has been heavily criticized based on this fact. Another study, which compared equipotent doses of esomeprazole (40 mg) and lansoprazole (30 mg), also suggests that esomeprazole has statistically significant greater healing rates (92.6% vs. 88.8%, respectively, $p = 0.0001$).[39] In contrast, a similar study comparing lansoprazole 30 mg with esomeprazole 40 mg showed no statistical difference in esophageal healing, albeit with a smaller population.[40] Dexlansoprazole MR 60 mg once daily has been compared with lansoprazole 30 mg once daily in randomized, double-blind clinical trials to assess healing of erosive esophagitis.[193] The results using life-table analysis reveal similar healing rates with dexlansoprazole MR 60 mg and lansoprazole 30 mg (92%–93% vs. 86%–92%, respectively), but the results were not statistically significant.[193] A higher dose of dexlansoprazole MR (90 mg daily) was superior to lansoprazole (30 mg daily) in patients with more severe disease (Los Angeles Classification grades C and D), but these are not equipotent doses. In spite of the lack of supportive evidence, some clinicians prefer to use esomeprazole 40 mg/day or dexlansoprazole MR 60 mg/day for patients with severe erosive esophagitis.

The ability of a high-dose PPI to reverse Barrett metaplasia remains controversial.[6,194] Although studies have demonstrated islands of normal squamous epithelium returning, no data have determined that this is associated with a risk reduction in adenocarcinoma.[6,194] In fact, others have suggested that this return of normal mucosa may actually mask carcinogenic changes occurring deeper in the gastric mucosa.[195]

Improvement in quality of life has also been evaluated in patients receiving PPI therapy in the management of GERD. A recent study comparing esomeprazole with ranitidine during a period of 6 months showed a significant improvement in both physical functioning and sleep with the PPI therapy.[196]

PROKINETIC AGENTS

Two prokinetic agents, metoclopramide and bethanechol, may be effective in the management of GERD. Both drugs increase LES pressure and stimulate the motility of the upper GI tract without altering gastric acid secretion.[6] Although these drugs may provide relief of symptoms, they are ineffective in healing erosive esophagitis unless they are combined with an H_2RA or PPI. Prokinetics are not widely used to treat GERD because they are not as effective as other treatments and are associated with numerous side effects (sedation, anxiety, extrapyramidal symptoms, etc.).[6,156] Prokinetics are reserved for patients who are refractory to other available treatment options or who have delayed gastric emptying.

SUCRALFATE

Sucralfate appears to be effective in treating mild cases of GERD and possibly mild esophagitis but is not effective in the management of severe disease.[197] Given more effective options at this time, sucralfate is rarely used in the management of GERD.

PPIs are considered the drugs of choice for patients with frequent or severe GERD symptoms, or who have complicated disease, because of their potent inhibition of gastric acid secretion[65,153,179–181] (Fig. 23-5). In this case, L.F., who presents with severe esophagitis (Los Angeles grade C), will require a PPI taken once daily in order to relieve her symptoms and heal the esophagus (Table 23-1). A reasonable option for L.F. would be lansoprazole 30 mg daily to be taken 30 to 60 minutes before breakfast each

p. 508

---

p. 509

morning for the next 8 weeks; however, if the cost of therapy is an issue, generic omeprazole 40 mg daily would also be an acceptable alternative. L.F. should also be counseled regarding lifestyle and dietary modifications, including smoking cessation and abstinence from alcohol. She should avoid eating large meals before bedtime and may wish to elevate the head of her bed by 6 to 8 inches with wooden blocks.

Maintenance Therapy

CASE 23-4, QUESTION 3: L.F.'s symptoms resolved in about 2 weeks after starting PPI therapy, and she remained asymptomatic after 8 weeks. She then underwent endoscopy again, which revealed that the esophagus had healed completely. Her primary-care physician then stopped the PPI. Now, 2 weeks later, she is experiencing mild heartburn. Is L.F. a candidate for long-term maintenance therapy?

GERD is a chronic disease. Up to 80% of patients with severe esophagitis and 15% to 30% with less severe disease have a symptomatic relapse within 6 months after discontinuing treatment.[6] The goal of maintenance therapy is to keep the patient symptom-free and prevent potentially life-threatening complications. Continuous maintenance therapy with a daily PPI is more effective than an H_2RA, with reported relapse rates of 25% and 50%, respectively.[6] Thus, PPIs are the drugs of choice for maintaining remission in patients with healed esophagitis. An H_2RA may be considered for patients with mild nonerosive disease. Although one-half of the PPI dose used for esophageal healing has been suggested, guidelines indicate that the recommended maintenance dose should be the dose that is required to render the patient asymptomatic.[65,179] Maintenance therapy, to reduce the risk of morbidity associated with chronic, relapsing disease, should be initiated with lansoprazole 15 to 30 mg once daily or equivalent PPI dose given the severity of L.F.'s esophagitis and symptomatic recurrence after discontinuing the PPI.

On-Demand Pharmacotherapy

The use of intermittent (on-demand) courses of PPI therapy (2–4 weeks) has been suggested as being potentially beneficial in patients with GERD.[198–203] One trial, which compared continuous maintenance therapy with esomeprazole 20 mg daily versus on-demand therapy with the same drug and dose in patients with healed erosive esophagitis, reported that continuous therapy was superior to on-demand therapy (81% vs. 58%, respectively) in maintaining endoscopic remission at 6 months.[203] The ability to maintain remission with on-demand therapy was reduced as the severity in esophagitis increased. Although numerous studies with a variety of PPIs have demonstrated patient satisfaction with on-demand therapy,[199–202] a systemic review of 17 trials evaluating the use of on-demand therapy indicates that intermittent therapy should only be considered in patients with mild, nonerosive disease.[198]

Combination of a Proton-Pump Inhibitor and Histamine-2 Receptor Antagonists

The addition of an H_2RA at bedtime to a once or twice daily PPI regimen is sometimes used for patients who continue to have nocturnal symptoms, although the evidence to support this combination remains inconclusive and current guidelines do not endorse this type of antisecretory management strategy at this time.[65] The rationale for this practice is based on an evidence that suggests a period of nocturnal acid breakthrough (defined as intragastric pH <4 for longer than 1 hour during the night) in a significant number of patients despite twice-daily PPI therapy, suggesting that histamine release may have an important function in nocturnal acid secretion.[204] One study suggests that the addition of an H_2RA to a twice-daily PPI regimen resulted in a statistically significant reduction in nocturnal acid breakthrough during the sleeping hours.[204] This trial, however, evaluated only a single bedtime dose of an H_2RA and did not consider the tachyphylaxis that can occur with continuous use. A subsequent trial using a twice-daily PPI regimen with continuous use of an H_2RA for 4 weeks demonstrated no difference in nocturnal acid suppression, suggesting that tolerance does play an important role in the use of H_2RAs for this indication.[26] It has been theorized that one way to possibly avoid this occurrence is to use the H_2RA on only an as-needed basis when lifestyle and dietary modifications are not effective for preventing nocturnal symptoms.[6]

Nonerosive Reflux Disease

Up to 75% patients with typical GERD symptoms who undergo endoscopy will not have evidence of esophagitis or complicated disease.[158] These patients are described as having functional heartburn, NERD or ENRD, and often undergo 24-hour ambulatory pH monitoring to determine whether abnormal reflux is present despite a negative endoscopy. A trial of a PPI is usually indicated despite no esophageal findings, because many patients will respond to this therapy.[158] Further medical evaluation is required if a patient does not respond to PPI therapy despite a doubling of the daily dose.

Extraesophageal Manifestations

CASE 23-5

QUESTION 1: S.P. is a 71-year-old retired man who was eating dinner with his wife when he experienced a sudden onset of chest pain described as crushing, burning, and squeezing. His wife notified emergency personnel, who transported S.P. to the emergency department. His past medical history reveals some cardiovascular risk factors, including age, hypertension, hyperlipidemia, and a sedentary lifestyle. His medications before admission include aspirin 81 mg daily, hydrochlorothiazide 25 mg daily, and atorvastatin 40 mg at bedtime. He also takes OTC famotidine 20 mg daily as needed for dyspepsia. On examination, he complains of substernal crushing chest pain that has lasted more than 1 hour. He is diaphoretic and extremely anxious. He denies any shortness of breath, pain radiating to upper extremities or jaw, or cough. His vital signs include a temperature of 99.1°F, blood pressure of 155/95 mm Hg, and heart rate of 115 beats/minute. Pertinent laboratory results at this time are

White blood cell (WBC) count, 7,700/µL
Hgb, 14.2 g/dL
Hct, 45%
Platelets, 270,000/µL
SCr, 1.1 mg/dL
BUN, 11 mg/dL
Total cholesterol, 161 mg/dL
Low-density lipoprotein, 93 mg/dL
High-density lipoprotein, 30 mg/dL
Triglycerides, 190 mg/dL
Sodium, 141 mEq/L
Potassium, 4.1 mEq/L
Troponin I, 0.3 ng/mL

Electrocardiogram reveals sinus tachycardia with no evidence of ST-segment elevation, depression, or T-wave inversion or new left bundle branch block. Because of S.P.'s cardiovascular risk factors and indeterminate troponin, he underwent immediate diagnostic cardiac catheterization, which showed normal coronary angiography and an ejection fraction of 65%. S.P. was diagnosed with noncardiac chest pain (NCCP). Could S.P.'s chest pain be associated with an extraesophageal manifestation of GERD?

Extraesophageal (atypical) manifestations of GERD are those signs and symptoms that occur outside of the esophagus yet are presumed to be associated with GERD. The extraesophageal manifestations of GERD include NCCP; pulmonary symptoms; and complaints related to the ear, nose, and throat; as well as hypersalivation and dental erosions (Table 23-10). Interestingly, these symptoms are often the only complaint that a patient has when he or she presents to the health-care provider.[6,205]

NONCARDIAC CHEST PAIN

About 30% of patients with angina-like chest pain have normal coronary arteries or minimal microvascular disease as demonstrated by cardiac angiography.[206] Up to 60% of these patients will have concomitant GERD as demonstrated by an abnormal esophageal endoscopy or ambulatory pH monitoring.[6,206] The symptoms associated with NCCP are very similar to those associated with cardiac angina. The chest pain is usually described as crushing, squeezing, or burning; retrosternal in location; and with or without lateral radiation to the upper extremities, back, neck, or jaw. The pain is often temporarily related to a meal or occurs nocturnally, usually awakening the patient and continuing for hours. An appropriate workup for coronary artery disease must be performed in all patients presenting with chest pain before considering a GI cause or trial of antireflux therapy.[65,206] This is especially important in women, the elderly, and diabetic patients, because their initial presentation may be similar to GI complaints when in fact an acute coronary syndrome is present. Numerous trials have evaluated the use of acid suppression as a means to treat NCCP once cardiac etiology has been ruled out through appropriate evaluation.[206–208] Meta-analyses and guidelines have suggested the PPI test, in which a short course (4 weeks) of high-dose (twice-daily) PPI is used, is an effective diagnostic tool and is associated with a reduction in costs compared with other diagnostic methods of GERD.[65,207,208]

Table 23-10

Atypical Manifestations of Gastroesophageal Reflux Disease[6,205]

Noncardiac Chest Pain	**Pulmonary**
Ear, Nose, and Throat Laryngitis/pharyngitis	Chronic cough Nonallergic, nonseasonal asthma
Hoarseness	Aspiration
Globus sensation	Bronchiectasis/bronchitis
Laryngeal cancer	Sleep apnea
Sinusitis	Idiopathic pulmonary fibrosis
Otitis	Pneumonia
Other	
Hypersalivation Dental erosions	

ASTHMA AND GASTROESOPHAGEAL REFLUX DISEASE

Reports suggest that concomitant GERD occurs in up to 80% of the asthmatic population through two theoretical mechanisms that might work to exacerbate asthma symptoms.[209] One is the vagal reflex theory, which proposes that symptoms result from the direct irritation of the vagus nerve when refluxate comes into contact with the esophageal mucosa, resulting in reflex bronchospasm.[210,211] In contrast, the microaspiration or reflux theory proposes that aspiration of refluxed acid into the lungs causes caustic injury of tissue within the bronchial tree, resulting in asthmatic symptoms.[211,212] Significant controversy exists regarding the benefit of antireflux pharmacotherapy in patients with asthma, especially in those patients who do not endorse typical GERD symptoms. An important meta-analysis of trials that evaluated the effects of antireflux therapy on patients with asthma indicates that asthma symptoms improved in 69% of patients, that the use of asthma medications was reduced by 62%, and that only 26% of the subjects showed improvement in evening peak expiratory flow rate. All other pulmonary function tests showed little or no change with antireflux therapy.[213] However, this meta-analysis only evaluated studies of up to 8 weeks in duration. A large randomized, double-blind trial evaluated esomeprazole 40 mg twice daily versus placebo for 6 months in patients with poorly controlled asthma managed with inhaled corticosteroids, who lacked typical GERD symptoms. Results revealed no benefit in asthma control with the addition of a PPI, despite 40% of subjects demonstrating GERD by ambulatory pH monitoring.[214] Current American Thoracic Society/European Respiratory Society guidelines for the management of severe asthma suggest that GERD and antireflux therapy can be considered in patients with poorly controlled asthma, if they have GI symptoms consistent with GERD.[215] The American Gastroenterological Association position statement accepts the use of an empiric trial of twice-daily PPI for asthmatic patients with typical GERD symptoms, but that reflux monitoring should be considered before PPI trial in asthmatic patients with atypical GERD symptoms.[156]

OTOLARYNGOLOGY SYMPTOMS AND GASTROESOPHAGEAL REFLUX DISEASE

GERD is the most common etiologic factor in 60% of patients with chronic laryngitis and in 25% to 50% of patients with a globus sensation (the feeling that something is caught in the throat).[216] Symptoms relating to GERD are responsible for up to 10% of the patients seen by otolaryngologists.[216] The most likely mechanism for the pathophysiology of GERD-related laryngitis is that damage and inflammation occur at night while the patient is sleeping. It is during this time when upper esophageal sphincter pressures are especially low and the protective or neutralizing mechanisms of cough and salivation are suppressed.[217] This damage may be in addition to injury or laryngeal inflammation sustained from other causes, such as excessive voice usage, smoking, chronic throat clearing or cough, vomiting, or injury from endotracheal tubes.[205,218] The extent of injury in GERD-related hoarseness is directly related to the exposure time of the pharyngeal mucosa to the refluxate as well as the pH. Patients with GERD-related hoarseness usually do not have any other GERD-related symptoms.[205] The diagnostic procedure of choice is laryngoscopy and should be considered in all patients presenting with GERD-related hoarseness. Once the diagnosis of GERD-related hoarseness or laryngitis is established, the patient will likely require extended high-dose PPI therapy with the understanding that the majority of patients will relapse within 6 weeks once therapy is discontinued.[219]

TREATMENT FOR THE EXTRAESOPHAGEAL MANIFESTATIONS OF GASTROESOPHAGEAL REFLUX DISEASE

Experts suggest that treatment should be initiated with a high-dose (twice-daily) PPI for at least 3 months before considering drug therapy to be ineffective; however, data are lacking to support this recommendation with the exception of noncardiac chest pain.[65] Recent guidelines suggest this empiric strategy is acceptable if concurrent typical GERD symptoms are present.[65] Alternatively, it is possible that GERD may not be the cause of the patient’s symptoms.

S.P.’s chest pain is not of cardiac origin based on angiographic findings. Therefore, it is reasonable to presume that he is having an extraesophageal manifestation of GERD. S.P.’s symptoms were meal related, and he has a history of dyspepsia for which he takes an OTC H_2RA. The H_2RA should be discontinued, and S.P. should be given a trial of empiric twice-daily PPI therapy for a period of 2 to 4 weeks. If symptoms are severe, the use of endoscopy (to determine if esophageal damage is present) or 24-hour esophageal pH monitoring (to correlate reflux events with symptomatic chest pain) is appropriate.

Antireflux Surgery

CASE 23-5, QUESTION 2: S.P. responded well to the trial of omeprazole 40 mg orally twice daily and has not had chest pain in 2 months. He has heard that surgical options exist that may eliminate his need for medications, as they are very expensive for him. Is S.P. a candidate for antireflux surgery?

Numerous surgical and endoscopic procedures exist for patients with GERD. These include, but are not limited to, Nissen fundoplication, Toupet partial fundoplication, Belsey Mark IV repair, and the Hill posterior gastropexy repair, as well as newer endoscopic techniques.[7] The primary goal of these procedures is to restore LES pressure by repairing a hiatal hernia or diaphragmatic hiatus. Appropriate candidates include patients who are in a good health and request another treatment option as a result of poor medication adherence, patients who are unable to afford their medication, patients who suffer from side effects or worry about risks with long-term therapy, patients with extraesophageal symptoms who have responded well to antireflux therapy, or patients experiencing volume regurgitation and aspiration of gastric contents who have not responded to PPI therapy.[6,65,148,188] Despite the availability of these surgical options, the consideration of antireflux surgery is one in which the benefits should be heavily weighed against the risks of such an invasive approach, because these procedures are not without potential complications. The effectiveness of these procedures has been questioned, because many patients will still require drug therapy.[6,65] S.P. has responded well to high-dose PPI therapy for his NCCP, but he describes some financial difficulties with affording his medications. Alternatively, he is 64 years of age, which may increase the risk associated with surgery. S.P. should be referred for further medical evaluation to determine whether he is a candidate for antireflux surgery.

UPPER GASTROINTESTINAL BLEEDING

Upper GI bleeding is a common medical emergency that occurs in up to 160 cases per 100,000 adults annually and is associated with increased morbidity and mortality as well as substantial costs to the health-care system.[220,221] Despite advances in endoscopic hemostatic therapy and pharmacotherapy, the mortality rate associated with upper GI bleeding remains at 5% to 15%, which is the same as it has been for the last 20 to 40 years.[2,3,220,221] Upper GI bleeding can be categorized as either variceal or nonvariceal bleeding (see Chapter 25, Complications of End-Stage Liver Disease). Nonvariceal bleeding describes bleeding associated with PUD or stress-related mucosal bleeding (SRMB). Other causes include erosive esophagitis, Mallory–Weiss tear (a tear near the gastroesophageal junction associated with retching or coughing), and malignancy.[4] Although PUD and SRMB are both acid-related disorders, their presentation and pathophysiology differ.

Peptic Ulcer Bleeding

EPIDEMIOLOGY

The majority of upper, nonvariceal GI bleeding is caused by PUD.[3,4,220,221] Bleeding ulcers account for more than 400,000 hospitalizations in the United States each year.[221] As mentioned, the mortality rate for peptic ulcer bleeding can be as high as 15%. It has been suggested that an older presenting patient population (>60 years of age) with a greater number of comorbidities may account for this continued high mortality rate.[2,220,221] Fortunately, the vast majority (80%) of upper GI bleeding events are self-limited and require only minimal intervention.[2] National data derived from an U.S. database demonstrate a decreasing mortality rate (3.54%) in complicated elderly patients during 2001 to 2009.[222] Length of stay has been dramatically reduced in the majority of patients who receive early endoscopy (within 24 hours of admission).[220,221] However, in the 20% to 25% of patients who continue to bleed or rebleed after appropriate intervention, mortality increases to nearly 40%.[4,223]

PATHOPHYSIOLOGY

The most common causes of upper GI bleeding in patients with PUD are NSAID use and H. pylori infection.[87] Bleeding occurs when an ulcer extends deeper into the mucosa and erodes the wall of a blood vessel.[224] The incidence of H. pylori infection in bleeding ulcers is 15% to 20% lower than in patients with nonbleeding ulcers.[224] Bleeding associated with PUD is generally not caused by the hypersecretion of gastric acid, with the exception of patients with ZES.[224] The pathophysiology and risk factors associated with PUD are described earlier in this chapter (see section on Peptic Ulcer Disease).

CLINICAL ASSESSMENT AND DIAGNOSIS

The clinical presentation of a patient with a bleeding peptic ulcer usually includes the presence of melena (dark, tarry stools), which occurs in 20% of patients, hematemesis (vomiting of blood) in 30%, and both in about 50% of patients. Up to 5% of patients present with hematochezia (bloody diarrhea) indicative of rapid and substantial blood loss.[224] The primary step in evaluating the patient is to assess the degree of urgency for rapid medical management.[224] Two validated prognostic scales exist for early risk stratification into high-risk or low-risk adverse outcomes for patients presenting with upper GI bleeding. The pre-endoscopy Rockall score and Glasgow–Blatchford score utilize laboratory and clinical characteristics of the patient to assist the clinician in determining the need for and emergent nature of endoscopy in the individual patient.[4,220,221] The complete Rockall score, which includes data from the endoscopy, is used to predict the likelihood of rebleeding after endoscopy and mortality.[4,220,221] Hypovolemia owing to substantial blood loss can rapidly lead to shock. The initial management of these patients should focus on volume resuscitation and improving the patient's hemodynamic status. Clinical features suggestive of high risk for rebleeding or mortality include patients older than 65 years, serious comorbidities (e.g., hepatic or renal dysfunction, cardiac or pulmonary disease),

hemodynamic instability (e.g., hypotension, tachycardia), shock, poor health, continued bleeding, mental status changes, and prolonged prothrombin/activated partial thromboplastin time (aPTT) (or elevated international normalized ratio [INR]).[2,4,220,223–226] These patients should immediately be transferred to an intensive care setting.

Most patients should receive early diagnostic endoscopic evaluation within 24 hours of presentation to determine the source of the bleeding, to predict the risk for rebleeding, and when required, to perform endoscopic interventions directed at stopping the bleeding ulcer and restoring hemostasis.[220,221] Risk of rebleeding may be predicted based on the presenting lesion(s) identified on endoscopy.[4,224] The most common ulcer identified on endoscopy is a clean-base ulcer found in about 42% of patients. This ulcer has a very low risk of rebleeding (5%), and the patient can usually be discharged immediately after recovery from the endoscopy and managed with appropriate antisecretory therapy. Intermediate stigmata of bleeding include lesions identified as flat-spot ulcers and/or adherent clots, which have a risk of rebleeding of 10% and 22%, respectively. Although endoscopic procedures are not usually necessary with flat-spot ulcers, adherent clots remain an area of controversy and usually require the endoscopist to attempt to remove the clot and manage the underlying lesion.[220] Patients identified with high-risk ulceration (nonbleeding visible vessel or active bleeding) will require endoscopic intervention and have a high risk of rebleeding (43% and 55%, respectively) despite intervention. Nonbleeding visible vessel and active bleeding are associated with an 11% mortality on initial presentation.[224] Ulcer size is also predictive of mortality and rebleeding, because ulcers greater than 1 or 2 cm in diameter confer greater risk.[224] Despite appropriate endoscopic hemostasis, approximately 20% of patients with peptic ulcer bleeding will rebleed within 48 to 72 hours after treatment.[4,220,223,224] Mortality associated with rebleeding is about 30% to 37%.[223] Patients undergoing endoscopy should be tested for H. pylori infection with biopsy (rapid urease test), because infection with this organism is associated with an increased risk of rebleeding.[220,221] Because false negatives can occur in the presence of active bleeding, all H. pylori–negative patients should have a confirmatory follow up test with serologic antibody testing on discharge to ensure that the patient is not infected.[220]

TREATMENT

Patients with upper GI bleeding require rapid risk stratification based on the presenting signs and symptoms. Patients with hemodynamic instability require immediate institution of resuscitative measures.[4,220,221,227] IV access should be obtained with two large-bore (e.g., 16–18 gauge) catheters to facilitate the administration of fluids and blood products.[4,221] Intravascular volume should initially be replenished with normal saline to prevent the patient progressing into hypovolemic shock. During this time, blood can be typed and crossed in the event a transfusion is required. Guidelines recommend the transfusion of packed red blood cells for patients with a Hgb level of less than 7 g/dL; however, consideration is warranted in the patient with tachycardia or hypotension and a Hgb level of 10 g/dL.[220,221] A nasogastric tube should be placed to allow for lavage and determination of the upper GI tract as the source of the bleed and evaluation of continued bleeding.[4,220,221,227]

Endoscopic evaluation with hemostatic techniques (when required) should be performed as soon as safely possible.[220,221] Endoscopic hemostasis is the cornerstone of management of patients with serious bleeding ulcers, because it reduces the incidence of rebleeding, the need for surgery, and mortality when compared with placebo or drug therapy.[220,221] Endoscopic procedures include thermocoagulation, laser therapy, injection therapy (epinephrine, ethanol, or saline), injection with sclerosing agent, or placement of endoscopic clips. Combining thermocoagulation with injection therapy is superior to either therapy alone or hemoclipping alone in patients with serious ulcer bleeding.[4,220,221] Despite initial hemostasis, however, the potential for rebleeding remains high, especially in patients with high-risk lesions.[4,220–224]

Improvements in hemostatic parameters (e.g., platelet aggregation, inactivation of pepsin, and correction of coagulation) leading to clot stabilization correlate directly with an intragastric pH greater than 6.[221,222,225] Therefore, treatment with an antisecretory drug is beneficial in patients after endoscopy to promote healing of the lesion. After the acute phase, the patient should be placed on appropriate drug therapy to continue healing and prevent ulcer recurrence (see section on Peptic Ulcer Disease). Patients who are H. pylori positive should receive appropriate eradication pharmacotherapy and confirmation of eradication at a later time.[220]

Histamine-2 Receptor Antagonists

Once widely used to manage upper GI bleeding, H_2RAs are now considered inferior to PPIs for reducing the incidence of rebleeding and the need for surgery.[220,221] This is likely related to the inability of H_2RAs to achieve an intragastric pH greater than or equal to 6 (even with continuous IV administration) and the rapid development of tachyphylaxis (especially with high IV doses).[220,225,29] Thus, H_2RAs are no longer recommended for the prevention of rebleeding associated with a peptic ulcer.[220,221]

Proton-Pump Inhibitors

PPIs are the drugs of choice to reduce the incidence of PUD-related rebleeding and the need for surgical intervention.[4,220,221,228–230] However, no clinical trials were able to show a mortality benefit with PPIs when entire treatment cohorts were evaluated.[228–230] Two meta-analyses performed by the Cochrane Collaborative group evaluating PPIs administered IV or orally against H2RAs or placebo showed a reduction in rebleeding, surgery, and repeat endoscopic treatment. [228,229] Based on these available data, PPI therapy for peptic ulcer bleeding is superior to H_2RAs and placebo.[220] Although no reduction in the number of deaths were identified when all patients were considered, PPI treatment of patients at the highest risk of mortality, as evidenced by endoscopically determined active bleeding or nonbleeding visible vessel, did impart a mortality benefit.[229] All-cause mortality was also reduced in Asian trials, with a concomitant greater reduction in the incidence of rebleeding and need for surgery than in trials performed elsewhere in the world. This may be explained by the inclusion of a younger patient population, more potent acid suppression because of genetic polymorphism in CYP450 metabolism leading to a slower clearance of PPIs, a lower parietal cell mass, and a greater incidence of H. pylori infection.[228]

Despite the data, important questions remain as to the most appropriate dose and route of administration for PPIs in patients with peptic ulcer bleeding. Evidence suggests that most patients with low-to-intermediate risk lesions (clean-base or flat-spot ulcers) and who are hemodynamically stable may be treated with oral PPIs and immediately discharged after endoscopy, because rebleeding is infrequent in this population.[220,228,231] Patients with adherent clots and high-risk bleeding ulcers (active bleeding and nonbleeding visible vessels) are typically managed with high-dose bolus and continuous infusion of a PPI (omeprazole 80 mg or equivalent PPI followed by 8 mg/hour for 72 hours of omeprazole or an equivalent PPI) as recommended by the current treatment guidelines.[220] However, a recent meta-analysis has called into question the need for high-dose PPI therapy.[232] This meta-analysis evaluated over 1,300 patients enrolled into 10 randomized controlled trials treated with intermittent or continuous infusion PPIs. The risk ratio of rebleeding within 7 days of therapy was 0.72 with an upper boundary 1-sided 95% confidence interval of 0.97

suggesting non-inferiority of intermittent PPI dosing. These results will need to be confirmed with a carefully designed randomized controlled trial. Finally, another meta-analysis has also suggested that PPI therapy is associated with reduced blood transfusion requirements.[233] Some patients may be switched to an oral PPI if rapid stabilization occurs, but careful clinical assessment should be performed to ensure the patient is stable.[231] Early initiation of a PPI bolus infusion before endoscopy has been shown to reduce the proportion of patients with active bleeding once endoscopy is performed, reduce the requirements for endoscopy, and reduce hospital stay.[234] However, this strategy should not replace early endoscopic management in high-risk patients, because combination PPI therapy with endoscopic maneuvers has been proven to be more effective than monotherapy with an IV PPI.[220,221,235]

Once the high-risk patient has stabilized and is considered safe for discharge after endoscopy and 72 hours of IV PPI, the patient should be discharged with a prescription for at least once-daily PPI pharmacotherapy for continued healing of the lesion and further prevention of rebleeding.[220] The actual dose and duration, however, should be decided based on the patient's severity of disease and identified complications, with more severe disease warranting consideration of twice daily therapy.[220] Patients who are required to remain on cardioprotective aspirin or NSAID therapy may require long-term secondary prophylaxis in an attempt to prevent future upper GI bleeding events.[220]

Other Agents

The use of somatostatin or octreotide is not recommended for the treatment of patients with nonvariceal upper GI bleeding, because there is no evidence of benefit to support their use.[220,221] However, these agents are commonly used in the management of variceal bleeding (see Chapter 25, Complications of End-Stage Liver Disease).

Stress-Related Mucosal Bleeding

Acute SRMB is a type of erosive gastritis that occurs in critically ill patients with severe physiologic stress (e.g., surgery, trauma, organ failure, sepsis, severe burns, and neurologic injuries).[229,236–239] The term stress ulcer is a misnomer in that SRMB may range from numerous diffuse superficial erosive mucosal lesions (those that do not penetrate the muscularis mucosa) to major deep ulceration (penetration of the muscularis mucosa and potentially submucosa).[240,241] Initial lesions occur early (<24 hours) and appear as subepithelial petechiae that can develop into superficial erosions and ulcerations.[239,240] Early stress-related mucosal lesions are multiple, usually asymptomatic, without perforation, and commonly bleed from superficial mucosal capillaries.[238,240] The gastric fundus is the most likely anatomic region of the stomach to be involved. Distal lesions involving the gastric antrum and duodenum have also been described but tend to appear later in the hospital course and are often deeper and associated with a greater probability for bleeding.[240] SRMB from these lesions may be categorized into three distinct types based on clinical presentation.[238–241] Occult (hidden) bleeding is defined as aspirated gastric fluid or stool that is guaiac-positive for the presence of occult blood and without other signs or symptoms. Overt bleeding is defined as frank hemorrhage identified by hematemesis (bloody vomitus or the appearance of coffee grounds in gastric aspirates or vomitus), hematochezia (bloody diarrhea), or melenic stools. Clinically important bleeding or life-threatening bleeding is the presence of overt bleeding that is associated with hemodynamic changes (tachycardia, hypotension, orthostatic changes, or Hgb concentration decline of >2 g/dL) and the requirement of transfusion of blood products. Endoscopic therapy is generally not a viable option because of the extensive distribution of lesions associated with SRMB.[236]

EPIDEMIOLOGY

The majority (>75%) of the critically ill patients admitted to intensive care units (ICUs) will exhibit mucosal lesions consistent with SRMB within 24 hours of admission.[236,238–241] Only a small percentage (up to 6%) of these patients will progress to clinically important GI bleeding.[238–241] Clinically important SRMB has been associated with an increased length of stay in the ICU by up to 11 days and results in substantial increases in the cost of healthcare.[236,238–240,242] The mortality of clinically important SRMB approaches 50%, but mortality may also be associated with underlying comorbidities related to the critical illness.[229,239]

PATHOPHYSIOLOGY

Numerous factors have been identified in the pathogenesis of SRMB and resultant bleeding. These include gastric acid and pepsin secretion, disruptions to the normal homeostatic mechanisms that protect the gastric mucosa against the highly acidic environment (decreases in prostaglandin, bicarbonate, and GI mucus formation as well as impaired turnover of gastric epithelium), GI motility disturbances, and mucosal ischemia resulting from decreased blood flow.[236,238,239,241] Gastric acid is likely the central factor associated with development of SRMB.[236,240] Because of the absence of protective defenses, substantial amounts of acid are not required for the formation of lesions, but some acid is required for damage to occur.[241] Although some patients may have increased acid secretion (e.g., sepsis, CNS injuries, small bowel resections), the majority of critically ill patients have normal or decreased acid secretion.[237,240,241] Pepsin secretion is associated with the lysis of clots owing to its proteolytic action on fibrin.[236,243] Gastric prostaglandins play a key role in the cellular defense against gastric acid.[236] These prostaglandins are responsible for maintaining the integrity of the mucosal barrier by stimulating mucus and bicarbonate production; regulating blood flow; and, to some degree, inhibition of acid production. Mucosal ischemia secondary to splanchnic hypoperfusion also plays a large role in the pathogenesis of SRMB.[236,238,241] Mucosal ischemia is associated with reduced ability to neutralize hydrogen ions leading to intracellular acidosis within the mucosa and subsequent cell death. These factors all contribute to an imbalance by increasing injurious factors and reducing the protective mechanisms within the gastric fundus.

RISK FACTORS

CASE 23-6

QUESTION 1: J.S., a 58-year-old, 110-kg man was admitted to the medical ICU for severe necrotizing pancreatitis identified on abdominal computed tomography. The patient was immediately made "nothing by mouth" and started on imipenem/cilastatin 1,000 mg IV piggyback (IVPB) every 6 hours. He was given hydromorphone 1 mg IV every 3 hours as needed for pain. He subsequently exhibited shortness of breath on his third day after admission. He required intubation and was placed on a ventilator. A chest x-ray showed a left lower lobe infiltrate suggestive of hospital-acquired pneumonia. Antibiotic coverage was increased with the addition of ciprofloxacin 400 mg IVPB every 8 hours and linezolid 600 mg IV every 12 hours. He has a temperature of 103.5°F, heart rate of 115 beats/minute, and blood pressure of 70/40 mm Hg. Pertinent laboratory results at this time include the following:

WBC count, 38,000/μL
Hgb, 13.6 g/dL
Hct, 40%
Platelets, 150,000/μL
SCr, 1.3 mg/dL

BUN, 24 mg/dL
INR, 1.0
aPTT, 39 seconds
Aspartate aminotransferase, 292 units/L
Alanine aminotransferase, 305 units/L
Amylase, 508 units/L
Lipase, 624 units/L

In addition to the antimicrobials and initiation of fluid resuscitation, the critical care team is considering stress ulcer prophylaxis. What risk factors does J.S. have (if any) for SRMB, and is he a candidate for stress ulcer prophylaxis?

Numerous risk factors have been associated with SRMB[236–240] (Table 23-11). However, a large landmark, multicenter, prospective study involving more than 2,200 critically ill patients admitted to a medical ICU identified only the requirement of mechanical ventilation (respiratory failure) or coagulopathy as independent risk factors for development of clinically important bleeding.[244] Considering the cost associated with the reduction of risk related to SRMB, the authors concluded that only these two risk factors warrant the use of prophylactic therapy. Because not all risk factors impose the same level of risk, clinical guidelines and most practitioners recommend prophylaxis only when the patient is mechanically ventilated, has a coagulopathy, or when two or more of the remaining risk factors are present[236,237,239] (Table 23-11). J.S.'s risk factors include septic shock as evidenced by hemodynamic instability and mechanical ventilation. Therefore, a prophylactic regimen to reduce the risk of SRMB is appropriate.

TREATMENT

CASE 23-6, QUESTION 2: What options exist to prevent SRMB in J.S.?

Not all patients admitted to the critical care unit will require prophylaxis for SRMB. However, because mortality can be high in patients when bleeding occurs, evaluation of risk is of absolute importance to ensure that protective pharmacotherapy is initiated in appropriate patients.[236–241] Because acid is required for mucosal injury, the inhibition of gastric acid is the primary target when pharmacotherapy is used to reduce the risk of SRMB. An intragastric pH greater than 4 is the recommended goal of therapy.[229,236–241] Therapeutic options include the use of antacids, sucralfate, H_2RAs, and PPIs (Table 23-12).

Table 23-11

Risk Factors for Stress-Related Mucosal Bleeding[236–240]

- Respiratory failure
- Coagulopathy
- Hypotension
- Sepsis
- Hepatic failure
- Acute renal failure
- Enteral feeding
- High-dose corticosteroids[a]
- Organ transplant
- Anticoagulants
- Severe burns (>35% of body surface area)
- Head injury
- Intensive care unit stay >7 days
- History of previous GI hemorrhage

[a] Greater than 250 mg/day hydrocortisone or equivalent.

Antacids

The use of aggressive antacid therapy is superior to placebo in reducing clinically important SRMB when an intragastric pH greater than 3.5 is maintained.[236,238,239]

Although antacids are effective in preventing SRMB, their use has fallen out of favor because of difficult administration regimens (every 1–2 hours) with the continuous requirement of intragastric pH monitoring for dose titration, electrolyte abnormalities (especially in patients with renal dysfunction), diarrhea, constipation, and the potential risk of aspiration pneumonia.[236,238–240] These issues, coupled with the fact that potent acid suppression is available in far more convenient dosage forms, have all but eliminated the use of antacids as SRMB prophylaxis.[236]

Sucralfate

Sucralfate is effective in preventing SRMB but does not have an important effect on intragastric pH.[245,246] Despite the fact that antisecretory therapy is preferred, sucralfate remains an available therapeutic option. Early studies suggested a reduction in nosocomial pneumonia with sucralfate when compared with ranitidine or antacids. However, a subsequent randomized trial involving 1,200 mechanically ventilated patients revealed no increase in pneumonia with H_2RAs when compared with sucralfate or antacids.[247] The usual dose of 1 g 4 times daily can present problems within the critical care setting because of multiple daily dosing, binding of other enterally administered drugs, and occlusion of nasogastric tubes (may be reduced with suspension formulation). Other potential issues include the risk for aluminum toxicity in patients with renal failure, constipation, and electrolyte imbalances. The concomitant use of sucralfate with antisecretory therapy may reduce the effectiveness of sucralfate as an intragastric pH less than 4 is needed for conversion to its active form, which binds to the gastric mucosa.[239]

Histamine-2 Receptor Antagonists

H_2RAs are effective in preventing SRMB and are the most widely used for this indication.[248,249] Although only cimetidine continuous infusion has been FDA labeled for the prevention of SRMB, continuous or intermittent infusions of ranitidine and famotidine are most often used for this indication.[225,236,238] Continuous infusions have been suggested as being more effective in maintaining a pH greater than 4, but there are no data comparing these two treatment options with respect to clinical outcomes.[236,240] Despite this, intermittent dosing is used more commonly than continuous infusions for the prophylaxis of SRMB.[225,238,248,249]

Numerous meta-analyses have evaluated the effectiveness of H_2RAs for prophylaxis of SRMB.[250,251] Cook et al. reviewed 63 randomized trials and determined that prophylaxis with H_2RAs was associated with a statistically significant reduction in overt and clinically important upper GI bleeding when compared with no therapy and a significant reduction in overt bleeding when compared with antacids.[250] A trend toward reduced clinically important bleeding was identified when H_2RAs were compared with sucralfate, but this was not statistically significant. In another meta-analysis, ranitidine was shown to be of no benefit in preventing SRMB and increased the risk of pneumonia.[251] However, neither of these meta-analyses included the large study involving 1,200 mechanically ventilated patients that compared sucralfate, ranitidine, and placebo.[247] Despite these conflicting results, H_2RAs remain a recommended option for the prophylaxis of SMRB.[248,249] One shortcoming of H_2RAs is that tolerance may develop (within 72 hours) and thus theoretically lead to potential prophylaxis failure.[29] H_2RAs are eliminated renally, and dosage reductions may be required in patients with renal failure.

Table 23-12

Stress-Related Mucosal Bleeding Prevention: Regimens and Doses

Agent	Dose and Frequency of Administration	FDA Approval[a]
Antacid	30 mL PO/NG every 1–2 hours	No
Cimetidine	300 mg IV loading dose, then 50 mg/hour continuous IV infusion[b]	Yes
Famotidine	20 mg IV every 12 hours or	No
	1.7 mg/hour continuous infusion	No
Ranitidine	50 mg IV every 6–8 hours or	No
	6.25 mg/hour continuous infusion	No
Sucralfate	1 g PO/NG every 6 hours	No
Omeprazole	20–40 mg PO/NG[c] every 12–24 hours	No
Omeprazole/sodium bicarbonate powder for oral suspension	40 mg PO/NG initially, followed by 40 mg 6–8 hours later, then 40 mg PO/NG every 24 hours	Yes
Lansoprazole	30 mg PO/NG[c],[d] every 12–24 hours	No
Pantoprazole	40 mg IV/PO/NG[c] every12–24 hours	No
Esomeprazole	40 mg IV/PO/NG every 12–24 hours	No

[a] For prevention of stress-related mucosal bleeding.

[b] Not available in the United States

[c] Extemporaneously compounded in sodium bicarbonate.

[d] Oral disintegrating tablet.

IV, intravenous; NG, by nasogastric tube; PO, by mouth.

Proton-Pump Inhibitors

PPIs, because of their profound ability to inhibit gastric acid secretion and lack of tolerance to their antisecretory effect, would appear to be the preferred option for preventing SRMB. However, there is very little evidence to confirm their clinical superiority to H_2RAs for this indication. Numerous studies have compared PPIs with H_2RAs or placebo in critically ill patients in small populations using varied predetermined end points.[239,252] These studies suggest that PPIs provide greater acid suppression compared with H_2RAs and are likely to be as effective in preventing SRMB.[239,252] One study in 359 critically ill patients evaluated the use of immediate-release omeprazole suspension in bicarbonate given via nasogastric tube at a dose of 40 mg for two doses, then 40 mg/day versus IV cimetidine given as a 300-mg bolus and then infused at 50 mg/hour (dosing was adjusted for patients with renal dysfunction).[253] The results indicated that the PPI-bicarbonate suspension was associated with a greater mean time of intragastric pH greater than 4 than the cimetidine infusion but that the rate of clinically important bleeding did not differ between cimetidine (6.8%) and omeprazole (4.5%). The FDA considered the immediate-release omeprazole-bicarbonate suspension to be noninferior to cimetidine for the prevention of SRMB.[254] An extremely important analysis aimed at identifying the most appropriate dose for IV PPIs in SMRB prophylaxis was performed in more than 200 critically ill patients.[255] This analysis included five different dosing approaches of IV pantoprazole intermittent infusions (40 mg given every 8, 12, or 24 hours or 80 mg given every 12 or 24 hours) compared with cimetidine given as a 300-mg IV bolus immediately followed by a 50 mg/hour continuous infusion. The patients received a minimum of 48 hours of therapy with a maximum of 7 days. In all the study arms, pH control was achieved (defined as intragastric pH ≥ 4); however, in all the pantoprazole arms, pH control continued to improve from day 1 to 2, whereas a decline was noted in the cimetidine group, suggesting the occurrence of tachyphylaxis. No upper GI bleeding was noted in any patient during the trial regardless of treatment group assigned. The conclusions of this study demonstrated that patients may have adequate pH control with an initial IV dose of pantoprazole 80 mg followed by 40 mg IV every 12 hours. Finally, a recent meta-analysis that included 14 studies totaling ~1,700 patients evaluating the efficacy and safety of PPIs compared with H_2RAs demonstrated a statistically significant difference between the two options with respect to the important endpoints of overt or clinically important bleeding. There were no differences with regard to mortality or incidence of pneumonia.[252]

The incidence of nosocomial pneumonia in patients receiving PPI therapy undergoing cardiothoracic surgery has been evaluated in two retrospective cohort studies.[256,257] Patients receiving PPIs were at an increased risk for developing pneumonia even after data adjustments for various risk factors. Numerous alternative administration options exist for patients in the critical care setting who cannot take medications by mouth, have nasogastric tubes in place, or have difficulty swallowing[239,254,257] (Table 23-13). PPIs are becoming first-line therapy for the prevention of SRMB, but additional studies are needed to confirm the most effective dose and route of administration in order to obtain optimal clinical outcomes in patients at risk of SRMB.[238,248] The use of early enteral nutrition that is initiated within 48 hours of admission to the ICU has also been evaluated as a means of prophylaxis against SMRB.[258] This was demonstrated in a meta-analysis of 17 studies, which suggested that patients who require enteral tube feedings may not require additional forms of SRMB prophylaxis and may also have a reduced risk of pneumonia or death when compared with patients receiving an H_2RA-based SMRB prophylaxis regimen.[258] This meta-analysis, however, was only hypothesis generating and should be interpreted with care until a large controlled study is available to confirm these findings.

Table 23-13

Alternative Proton-Pump Inhibitor Administration Options[239,254,257]

	Omeprazole	Lansoprazole	Pantoprazole	Esomeprazole	Rabeprazole	Dexlansop
Capsule granules sprinkled on selected soft foods (i.e., applesauce)		✓[a]		✓[a]	✓[a]	✓[a]
Capsule granules mixed in water and flushed down NG tube				✓		✓[a]
Capsule granules mixed in juice (can be administered via NG tube if required)	✓[a]	✓[a]		✓[a]	✓[a]	✓[a]
Extemporaneous compound of PPI in bicarbonate for NG tube	✓	✓	✓			
Package for oral suspension	✓[a,b]	✓[a,c]		✓[a]		
Oral disintegrating		✓[a]				

tablet						
IV formulation	Not available in the United States	Removed from US market	✓[a]	✓[a]		

[a]Labeled by the FDA for this administration option.

[b]Omeprazole suspensions available in 20- and 40-mg packets with bicarbonate (1,680 mg); both contain same am bicarbonate, and two 20-mg packets cannot be substituted for one 40-mg packet.

[c]Not to be administered via NG tube, because occlusion of tube is possible.

IV, intravenous; NG, nasogastric; PPI, proton-pump inhibitor.

MONITORING

CASE 23-6, QUESTION 3: J.S. has been started on famotidine 20 mg IV every 12 hours. How should this pharmacotherapy be monitored for safety and efficacy?

The famotidine dose should be adjusted to maintain an intragastric pH greater than 4 and should be based on severity of the patient's illness, renal function, and intragastric pH measurements. The intragastric pH can be determined with an indwelling probe or by measuring the pH of nasogastric aspirates. The patient should be monitored for signs of bleeding (e.g., presence of blood or coffee-ground material in nasogastric aspirates, hematemesis, hematochezia, or melena), hypotension, reductions in Hgb or Hct, and thrombocytopenia.

CASE 23-6, QUESTION 4: During the next 6 days, J.S. improves and is subsequently removed from mechanical ventilation and transferred to the medical ward. He is now able to eat normally. Should J.S. be continued on SRMB prophylaxis?

Patients receiving prophylaxis for SRMB should be evaluated for the continued presence of risk factors. As the patient improves, the risk factors should in turn be reversed, and the need for SMRB prophylaxis should diminish. Factors such as extubation, correction of coagulopathies, discharge from the intensive care setting, and the ability to take oral feeding advocate the discontinuation of prophylaxis. Numerous studies have suggested that up to 54% of patients were ordered SRMB prophylaxis outside the ICU setting and without a compelling indication.[259] Erstad and colleagues surveyed 153 institutions within the United States and found that in 65% of the hospitals, more than 25% of patients remained on SRMB prophylaxis after discharge from the ICU.[260] This can lead to increased costs, the potential of the patient being discharged on medication for which there is no indication, and future potential adverse effects from the medication.[259] Because J.S. does not possess any risk factors for SRMB, famotidine should be discontinued at this time.

Lower Gastrointestinal Disorders

Toyin Tofade, Benjamin Laliberte, and Charmaine Rochester-Eyeguokan

CORE PRINCIPLES

INFLAMMATORY BOWEL DISEASE

CORE PRINCIPLES	CHAPTER CASES
1 Inflammatory bowel disease (IBD) is a generic classification for a group of chronic, idiopathic, relapsing inflammatory disorders of the gastrointestinal tract. Symptoms of IBD are thought to result from dysregulation of the mucosal immune system. By convention, IBD is divided into two major disorders, ulcerative colitis (UC) and Crohn's disease (CD).	**Cases 24-1, 24-2**
2 Ulcerative colitis (UC) is an inflammatory condition of the large intestine, but it can cause disturbances in other organ systems. It is typified by abdominal pain, chronic loose bloody stools, and fatigue.	**Case 24-1 (Questions 1, 2)**
3 Crohn's disease usually causes significant diarrhea without frank blood, abdominal pain, and weight loss. Extraintestinal symptoms such as skin lesions, arthralgias, and ocular inflammation occur more commonly with CD than UC. CD can affect any part of the gastrointestinal tract, but small and large bowel involvement is most common.	**Case 24-2 (Question 1)**
4 Treatment for both UC and CD are divided into two areas: induction treatment, which controls symptoms, and maintenance treatment, which prevents recurrences. Specific agents used for induction in IBD depend on the extent and location of disease.	**Case 24-1 (Questions 3–5, 8)**
5 Topically applied agents (suppositories, foams, enemas), specifically mesalamine products (5-aminosalicylic acid), are effective for induction in UC confined to the rectum (proctitis) or the distal colon.	**Case 24-1 (Question 6)**
6 Long-term use of corticosteroids for treatment of both UC and CD is not effective and can result in serious adverse effects; thus, other agents should be used for maintenance of remission.	**Case 24-1 (Questions 7, 9–11)**
7 Corticosteroids are used most often for induction in CD patients. Agents such as azathioprine, infliximab, or other agents are used to maintain remission.	**Case 24-2 (Questions 2, 3)**
8 Tumor necrosis factor blocking agents such as infliximab are used in patients who do not respond to less aggressive therapy. These agents	**Case 24-2 (Question 6)**

have a high acquisition cost and carry significant risks for developing infections. However, clinical trials have shown that they are generally more effective than other therapies.	
IRRITABLE BOWEL SYNDROME	
① Irritable bowel syndrome (IBS) is a common and often debilitating condition that involves abdominal pain, bloating, and defecation associated with a change in bowel habits (usually constipation or diarrhea). It is benign and has no long-term complications.	**Case 24-3 (Question 1)**
② The treatment goal is to improve global IBS symptoms, including abdominal discomfort, bloating, altered bowel habits, and overall well-being. Treatment for IBS is based on the predominant symptoms of the patient. For irritable bowel syndrome with constipation (IBS-C), an increase in dietary "soluble" fiber is recommended, such as psyllium followed by lubiprostone or linaclotide.	**Case 24-3 (Questions 2, 3)**

p. 518

---

p. 519

③ Pain and bloating or visceral hypersensitivity associated with IBS may respond to antispasmodic agents such as peppermint oil, hyoscyamine, low-dose tricyclic antidepressants, or selective serotonin reuptake inhibitors.	**Case 24-4 (Question 1)**
④ Treatment for irritable bowel syndrome with diarrhea (IBS-D) includes antimotility agents such as loperamide. The Food and Drug Administration (FDA) also approved the antibiotic rifaximin and eluxadoline, a controlled substance with mixed opioid receptor activity.	**Case 24-4 (Question 2)**

OVERVIEW OF INFLAMMATORY BOWEL DISEASE

Definition and Epidemiology

Inflammatory bowel disease (IBD) is a generic classification for a group of chronic, idiopathic, relapsing inflammatory disorders of the gastrointestinal (GI) tract. IBD is common in developed countries.[1] It is estimated that more than 1.5 million people in the United States have IBD, and the prevalence of these disorders ranges from 100 to 200 per 100,000 people for CD and 205 to 240 per 100,000 for UC.[2,3] By convention, IBD is divided into two major disorders: ulcerative colitis (UC) and Crohn's disease (CD).[1,3,4]

However, approximately 10% to 15% of patients with IBD have symptoms that defy this schema.[5] Both UC and CD frequently affect a similar group of patients

(Table 24-1).[2,6] Caucasians appear to have a higher incidence of IBD compared with Asians or African Americans. In particular, Jews of European descent may have up to a fourfold increase in the incidence of IBD. Studies have found trends toward an increased incidence of IBD with increased socioeconomic status and in urban compared with rural communities. Hypotheses for this trend include overcrowding, exposure to infectious agents, and lifestyle differences. Although both UC and CD are generally considered diseases of the young, with peak incidences from ages 15 to 30 years, there seems to be no significant sex preference for IBD.[3,7]

Etiology

The true cause of IBD is unclear; however, hypotheses for these disorders include a combination of genetic abnormalities, chronic infection, environmental factors (bacterial, viral, temperate climate, prior appendectomy, and dietary antigens), host or intestinal microbiome interactions, and other abnormalities of immunoregulatory mechanisms.[1] Whatever the mechanism, it is now generally agreed that the symptoms of IBD result from dysregulation of the mucosal immune system and from an interplay between genes and the environment.[3,8] A number of environmental exposures have been associated with IBD. Smoking has been the most consistent and most studied environmental factor associated with IBD. Interestingly, the effects of smoking are different between UC and CD, with smokers having a decreased risk of developing UC but an increased risk for CD.[9]

The theory of an infectious etiology for IBD remains controversial. Patients may be genetically predisposed to mucosal immune dysregulation, and either normal flora or bacterial pathogens may trigger the inflammatory response that leads to IBD. While no causal relationship has yet been found, further investigation on the role of gut flora is ongoing.[3,10]

Pathogenesis

Under normal conditions, the mucosal immune system interacts with luminal antigens and mucosal bacteria on a continuous basis to maintain a state of controlled inflammation. In IBD, genetic predisposition leads to immune response dysfunction, and an autoimmune cascade occurs. Thus, proinflammatory cytokines in the gut trigger an “attack” on the colonic mucosa by leukocytes and other factors, leading to edema, ulceration, and destruction of the tissue. Normal immune regulators fail to halt this process, and the disease progresses. This can be attributable to a lack of regulatory or suppressor cells, an enhanced numbers of T cells, or both.[11] Studies have demonstrated that an increase of proinflammatory cytokines, chemokines, prostaglandin, and reactive oxygen species leads to increased inflammation and tissue destruction.[1]

Table 24-1

Pathophysiological Differences Between Ulcerative Colitis and Crohn's Disease[1,2,4,14,15,19]

Characteristic	Ulcerative Colitis	Crohn's Disease
Incidence (per year)	6–12/100,000	5–7/100,000
Anatomic location	Colon and rectum	Mouth to anus
Distribution	Continuous, diffuse, mucosal	Segmental, focal, transmural
Bowel wall	Shortened, loss of haustral markings, generally not thickened	Rigid, thick, edematous, and fibrotic
Gross rectal bleeding	Common	Infrequent
Crypt abscesses	Common	Infrequent
Fissuring with sinus formation	Absent	Common
Noncaseating granulomas	Absent	Common
Strictures	Absent	Common
Abdominal mass	Absent	Common
Abdominal pain	Infrequent	Common
Toxic megacolon	Occasional	Rare
Bowel carcinoma	Greatly increased	Slightly increased

Clinical Presentation

A careful patient history, physical examination, and endoscopic and radiologic studies are necessary to determine the severity of IBD. Laboratory studies such as an increased ESR or C-reactive protein can also aid in the diagnosis, but no single marker is pathognomonic.

Extraintestinal manifestations of IBD that can cause significant morbidity include reactive arthritis, uveitis, ankylosing spondylitis, pyoderma gangrenosum, and primary sclerosing cholangitis.[12] Although their incidence varies, many of the extraintestinal manifestations of UC and CD are similar.[12]

Patients with IBD often require surgery to control symptoms. For patients with UC, surgery is often curative. In contrast, in patients with CD, the frequency of recurrent disease after surgery is high and anatomically correlates with the original pattern of the disease.[13] Other similarities and differences in the pathophysiology of these disease states are outlined in Table 24-1.[1,4,14,15]

ULCERATIVE COLITIS

UC usually presents as a shallow, continuous inflammation of the colon ranging from limited forms of proctitis (rectal involvement only) to disease involving the entire colon. Crypt abscesses consisting of accumulations of polymorphonuclear neutrophil (PMN) cells, necrosis of the epithelium, edema, hemorrhage, and surrounding accumulations of chronic inflammatory cells are typical in UC.[15] Fistulas, fissures, abscesses, and small bowel involvement are not present. The inflammation is limited to the mucosa, which presents as friable, granular, and erythematous, with or without ulceration. Most patients with UC experience a chronic, intermittent course of disease. Chronic, loose, bloody stools are the most common symptom of UC.[4,15] Other common complaints include tenesmus (urge to defecate) and abdominal pain. Patients with pancolitis usually have more severe symptoms than those with disease limited to the rectum. Generally, in studies determining goals for UC management, clinical assessment, endoscopic or radiographic evidence, and a recognized scoring system (Trulove or Whitt) were used to determine severity, relapse, or remission induction.[3] Mild UC is defined as fewer than four stools a day, no systemic signs of toxicity, and a normal erythrocyte sedimentation rate (ESR). Moderate disease is characterized by more than four stools a day but minimal evidence of systemic toxicity. Severe disease is defined as more than six bloody stools a day, fever, tachycardia, anemia, or an ESR greater than 30.[14,15] Proctitis is usually considered a separate type of UC for treatment purposes. Constipation can occasionally be the presenting symptom with proctitis. Relapses and remissions are common in UC, with up to 70% of patients with active disease relapsing within 1 year after induction treatment.

CROHN'S DISEASE

CD is a chronic, transmural, patchy, granulomatous, inflammatory disease that can involve the entire GI tract, from mouth to anus, with discontinuous ulceration (so-called skip lesions), fistula formation, and perianal involvement. The degree of colonic involvement is variable; however, the terminal ileum is most commonly affected. Intestinal involvement is characteristically segmented and can be interrupted by areas of normal tissue.

Patients usually present with abdominal pain and chronic, often nocturnal, diarrhea.[16] Weight loss, low-grade fever, and fatigue are also common. Three patterns of disease exist predominantly: inflammatory, stricturing, or fistulizing. These patterns are the primary determinants of the disease course and the nature of complications.[14] Typically, inflammatory disease is observed early in the disease course. Stricturing or fibrostenotic disease is characterized by narrowing of the ileum because of growth of scar tissue from persistent inflammation. Fistulizing disease is particularly difficult to treat and is the source of significant morbidity in CD patients. Enterocutaneous and enterorectal fistulae are common, but other types, such as enterovaginal, can occur. Fistulae can be excruciatingly painful, can be a source of infection, and can also exert significant psychosocial distress.[1,4,14] Generally, in studies determining goals for CD management, clinical assessment, endoscopic or radiographic evidence, and a Crohn's Disease Activity Index (CDAI) score were used to determine severity, relapse, or remission induction. Defining the severity of CD is a difficult, yet important, step in successful treatment. Current guidelines from the American College of Gastroenterology define mild-to-moderate CD as ambulatory patients who are able to tolerate oral feeding without signs of systemic toxicity. Moderate-to-severe disease is defined as patients with symptoms of fever, weight loss, abdominal pain, nausea and vomiting, or significant anemia. Severe fulminant disease refers to patients with persistent symptoms despite standard induction regimens or those with signs of severe systemic toxicity.[16] The disease course of CD is variable. Years of frequent relapses may be followed by complete remission.

Treatment

Treatment of IBD depends on both the anatomic location of the disease and the patient-specific factors such as coexisting medical conditions, medication adherence, lifestyle and dietary factors, and patient health literacy. Furthermore, the goals of therapy include (a) relieving symptoms (induction and maintenance of remission or preventing relapse); (b) improving quality of life; (c) maintaining adequate nutritional status; (d) minimizing the risk of cancer; (e) attaining mucosal healing; and (f) reducing the need for surgery or chronic corticosteroid use.[16–18] Most drug therapies for IBD have been tested for both UC and CD (Table 24-2).

AMINOSALICYLATES

Aminosalicylates were the first class of drugs to show benefits in IBD. The prototypical agent is sulfasalazine, which is composed of sulfapyridine (a sulfonamide antibiotic) linked by an azo bond to 5-aminosalicylic acid, or mesalamine (5-ASA). Lower intestinal bacteria cleave the azo bond and release 5-ASA (the active moiety) for localized action in the colon. Systemic absorption of the sulfapyridine is responsible for most of the drug's adverse effects, but contributes nothing to the therapeutic benefit. A significant number of patients discontinue this medication because of dose-dependent adverse effects, including nausea, vomiting, headache, alopecia, and anorexia. Patients taking sulfasalazine may also experience an orange discoloration of their urine, tears, and sweat that may stain clothing or contact lenses. Other idiosyncratic adverse effects include rash, hemolytic anemia, hepatitis, agranulocytosis, pancreatitis, and male infertility. Additionally, patients with a sulfa or salicylate allergy should avoid sulfasalazine.

Safer sulfa-free compounds that contain only 5-ASA have been developed with techniques to decrease systemic absorption and maximize local drug delivery. Significant efficacy advantages of any 5-ASA drug versus another have not been demonstrated.[19–21] Mesalamine products have been developed for both oral and rectal administration. Administration of mesalamine by retention enemas or suppositories is significantly more effective in the treatment of active distal colitis or ulcerative proctitis, respectively, than oral mesalamine or topical steroids.[17,19,22] Combination oral and rectal therapy for distal colitis or ulcerative proctitis are superior to either modality alone.[22] With the exception of abdominal pain, cramps, and discomfort, rectally administered mesalamine is well tolerated. Enemas or suppositories should be administered at bedtime, preferably after a bowel movement. Recent studies have confirmed that higher doses rather than a proprietary delivery system of mesalamine are associated with improved response.[23] New higher-dose formulations of 5-ASA (e.g., Lialda, Apriso) decrease the daily pill burden but may be expensive. Common adverse effects of the oral 5-ASA compounds are listed in Table 24-2. Interstitial nephritis has rarely been reported with chronic use of mesalamine, but the association remains controversial. A comparison of aminosalicylate compounds is provided in Table 24-3.

Table 24-2

Pharmacotherapy for Inflammatory Bowel Disease[3,12,13,17,19,21,78,79]

Drug	Indication	Quality of Evidence per ACG	Recommendation per ACG	Dose	Adverse Reactions	Co
Sulfasalazine	UC: mild-to-moderate induction	Moderate	Strong	See Table 24-3	N/V, diarrhea, HA, rash, body fluid discoloration, anemia, hepatotoxicity, pancreatitis, nephrotoxicity, thrombocytopenia	Hi ha de
	UC: mild-to-moderate maintenance	High	Strong

CORTICOSTEROIDS

Corticosteroids are the most commonly used agents in the treatment of acute flares in patients with moderate-to-severe IBD.[24] The anti-inflammatory actions of corticosteroids are well known, but how these translate into their full mechanism of controlling IBD is not completely understood. First-line treatment for moderate-to-severe active IBD includes doses of corticosteroid equivalent to 40 to 60 mg of prednisone.[25] Data are insufficient to demonstrate any difference between single versus divided oral doses or continuous versus intermittent bolus intravenous (IV) administration. IV doses should be equivalent to hydrocortisone 300 to 400 mg/day or methylprednisolone 48 to 60 mg/day.[25]

Topical steroids can serve as an adjunct in patients with proximal rectal disease who have failed topical 5-ASA therapy.[22] Oral enteric-coated budesonide is approved for the treatment of CD. Budesonide possesses a high degree of topical anti-inflammatory activity with low systemic bioavailability.[26] The Entocort EC formulation of budesonide delivers drug primarily to the ileum and ascending colon. Short-term corticosteroid-associated adverse effects may be less than with traditional agents, and its use up to 1 year seems to be well tolerated.[27] Compared with traditional corticosteroids, budesonide has a number of potential drug interactions owing to its metabolism via the cytochrome P450 3A4 system.[28] Studies suggest that budesonide is as effective as traditional corticosteroids for the treatment of mild-to-moderate CD localized to the right colon or ileum, and recent guidelines identify budesonide as the preferred agent in this situation.[17,29–31]

IMMUNOMODULATORS

Azathioprine (AZA) and 6-mercaptopurine (6-MP) may be used for the management of corticosteroid-dependent and quiescent IBD. AZA is converted to 6-MP, which is then metabolized to thioinosinic acid by thiopurine methyltransferase (TPMT), the active agent that inhibits purine ribonucleotide synthesis and cell proliferation. It also alters the immune response by inhibiting natural killer cell activity and suppressing cytotoxic T-cell function. AZA (1.5–2.5 mg/kg/day) and 6-MP (1–1.5 mg/kg/day) are used in the treatment of UC and CD in patients whose conditions have not responded to systemic steroids, or as “steroid-sparing” agents.[16,17,32] Because of the long onset of action of 6-MP and AZA, these agents should be reserved for maintaining remission. Adverse effects of 6-MP and AZA include rash, nausea, pancreatitis, alopecia, and diarrhea. Myelosuppression, especially neutropenia, may have a delayed onset, and clinicians should monitor the complete blood count monthly for the first 3 months of treatment, then every 3 months thereafter. Pharmacogenomic testing for TPMT before initiation is recommended.[16,19] Low levels of TPMT result in

reduced AZA and 6-MP clearance, thereby increasing the risk of severe myelosuppression and hepatotoxicity.

Methotrexate (MTX), a folate antagonist, impairs DNA synthesis. Data suggest that MTX (15–25 mg intramuscular [IM] weekly) may have a role for both initial and chronic treatment of CD. The onset and degree of effect is comparable to that with 6-

MP and AZA.[33] Most experts and recent guidelines suggest reserving MTX use for patients with CD intolerant of, or refractory to, 6-MP or AZA treatment.[17,34] Adverse effects with MTX include stomatitis, neutropenia, nausea, hypersensitivity pneumonitis, alopecia, and hepatotoxicity.

Cyclosporine (CSA), which selectively inhibits T-cell–mediated responses, has been used to treat severe, acute UC.[35] Because of serious adverse effects, CSA is usually reserved for patients with severe UC refractory to corticosteroids. A randomized controlled trial found equal efficacy (about 85% response) with a 2-mg/kg daily IV dose compared with the standard 4-mg/kg dose.[36] The emergence of the tumor necrosis factor drugs for IBD has caused CSA use to significantly decline.

ANTITUMOR NECROSIS FACTOR AGENTS

Infliximab

Infliximab is a recombinant chimeric monoclonal antibody that binds to human tumor necrosis factor (TNF) α, neutralizing its biological activity. Infliximab is indicated for inducing and maintaining remission in patients with moderate-to-severe active UC and CD refractory to other treatments.[37,38] Infliximab is effective for healing CD fistulae, with data showing that chronic treatment can maintain fistula closure and decrease the need for surgery.[39] The response to infliximab is usually rapid, often occurring within several days. Since infliximab is a monoclonal antibody, a number of immunologic-mediated adverse effects are associated with therapy. Antibodies to infliximab have been detected in up to 60% of CD patients using the drug, and emerging data suggest that patients who develop these antibodies may be at more risk, not only for infusion-related reactions but also for reduced efficacy over time.[40,41] Immediate infusion-related reactions such as fever, chills, pruritus, urticaria, and (rarely) severe cardiopulmonary symptoms can occur. Infectious complications, including pneumonia, cellulitis, sepsis, and cholecystitis have also been reported. All TNF α blockers carry black-box warnings for their risk of serious infections and malignancy, particularly lymphoma.[42]

Other Biological Therapies

Success with infliximab in IBD has led scientists to develop and test other biological therapies designed to either block pro-inflammatory mediators or enhance anti-inflammatory mediators in the gut. To date, four other biologic agents are approved in the United States: the fully humanized anti-TNF-α antibody adalimumab, pegylated humanized Fab′ fragments against TNF-α (certolizumab pegol), and the humanized α_4-integrin antibodies natalizumab and vedolizumab. Adalimumab is approved for the treatment of moderate-to-severe UC and CD and may be particularly useful in patients with an attenuated response to infliximab.[43] Certolizumab and natalizumab are approved for patients with moderate-to-severe CD, whereas vedolizumab was most recently approved for both moderate-to-severe UC and CD. These agents will be further discussed in Case 24-2.

The precise place in therapy of the newer biologic agents is controversial. Most experts consider infliximab the biologic agent of first choice with the other agents reserved for a loss or lack of efficacy or adverse effects.[44]

ANTIBIOTICS

Because an infectious etiology has been proposed for IBD, it stands to reason that antibiotics may have some utility.[4] However, most studies evaluating antibiotics have shown little benefit with the exception of ciprofloxacin or metronidazole in fistulizing disease and metronidazole in perianal or perhaps postoperative CD disease.[3,45,46] Common adverse effects with chronic, high-dose metronidazole include metallic taste and peripheral neuropathy.

NUTRITIONAL THERAPIES

Nutritional therapies for IBD have been used because dietary intraluminal antigens may stimulate a mucosal immune response.[4] Patients with active CD respond to bowel rest, total parenteral nutrition (TPN), or total enteral nutrition. Enteral nutrition, with elemental or peptide-based preparation, appears to be as efficacious as TPN, without its associated complications. Unfortunately, poor compliance often limits this modality. Such therapy is used more commonly in the pediatric population with mild-to-moderate CD.[47,48]

SUPPORTIVE THERAPY

Symptomatic management of IBD is important to the patient's quality of life. This includes pain relief and diarrhea control. Loperamide or diphenoxylate with atropine may be used to treat mild symptoms provided obstruction or toxicity is not evident.[49] Severe worsening of symptoms and abdominal distension may indicate toxic megacolon caused by the inability to empty rapidly produced secretory products of the bowel. Patients should be monitored for iron and vitamin B_{12} deficiencies, especially if ileal involvement is extensive or resection has been performed.

SURGERY

Surgery is indicated in the treatment of IBD when the patient fails to respond to medical management; demonstrates intestinal complications such as perforation, obstruction, hemorrhage, toxic megacolon, or fistula formation; fails to grow and develop at a normal rate; or exhibits carcinoma of the rectum or colon.[16,17,50] Furthermore, patients with UC for longer than 10 years or who demonstrate premalignant changes on rectal biopsy may be managed surgically as a prophylactic measure. In patients with CD, surgical intervention is common.

ULCERATIVE COLITIS

Pathophysiology and Clinical Presentation

CASE 24-1

QUESTION 1: A.C., a 24-year-old female college student, has had episodic, watery diarrhea, and colicky abdominal pain relieved by defecation for the past 9 months. Eight weeks before admission, the diarrhea increased to 3 to 5 semi-formed stools daily. The frequency of the stools gradually increased to 7 to 10 times a day 1 week ago. At that time, A.C. noted bright red blood in the stools. Stool frequency has now increased to 12 to 15 per day, although the volume of each stool is estimated to be only "one-half cupful." She feels a great urgency to defecate, even though the volume is small. She has not traveled outside the United States, has not been camping, and has not taken any antibiotics within the past 6 months. She is allergic to sulfa, and takes only occasional over-the-counter acetaminophen for body aches or headaches.

A.C. complains of anorexia and a 10-lb weight loss during the previous 2 months. For the past 4 months, she has had intermittent swelling, warmth, and tenderness of the left knee, which is unassociated with trauma. She denies any skin rashes or any difficulties with her vision. A review of other body systems and social and family history are largely noncontributory.

A.C. appears to be a slightly anxious and tired young woman of normal body habitus. She is 165 cm tall and weighs 51 kg. Her temperature is 100°F; her pulse rate is 105 beats/minute and regular. Physical examination is normal, except for evidence of acute arthritis of the left knee and tenderness of the left lower abdomen to palpation.

Stool examination shows a watery effluent that contains numerous red and white cells with no trophozoites. Stool cultures and an amebiasis indirect hemagglutination test are negative. Other laboratory values include the following results:

Hematocrit (Hct), 30%
Hemoglobin (Hgb), 8.1 g/dL
White blood cell (WBC) count, 17,500/µL with 82% PMNs
ESR, 72 mm/hour
Serum albumin, 2.8 g/dL
Alanine aminotransferase (ALT), 33 units/mL

Sigmoidoscopy showed evidence of granular, edematous, and friable mucosa with continuous ulcerations extending from the anus throughout the colon. What is the most likely cause of A.C.'s diarrheal illness, and what is the evidence for this?

A.C.'s presentation is typical of a patient with new-onset UC. Drug-induced (pseudomembranous colitis) and infectious (parasitic) causes of diarrhea have been ruled out by history (no travel outside the United States, no recent camping, no antibiotic use) and stool examination. As discussed previously, UC is an inflammation of the mucosal layer of the colon and rectum.[1] Characteristically, the inflammation does not extend beyond the submucosa, and transmural ulcers are rare. On examination, the mucosa appears erythematous and is friable. Differentiation from CD is made by endoscopic and radiologic evidence of continuous distribution of pathologic disease (as opposed to segmental), as well as the anatomic location (confined to colon and rectum).

A.C. presents with the classic triad of UC clinical symptoms: chronic diarrhea, rectal bleeding, and abdominal pain. Diarrhea is secondary to decreased colonic absorption of water and electrolytes and diminished colonic segmental contractions that normally serve to decrease the flow of bowel content. A good indication of the severity of a patient's disease is the volume of stool passed per day.[16] Because the severity of the disease increases, incontinence and nocturnal diarrhea commonly occur. Stools are usually soft, mushy, formed, and often contain small amounts of mucus mixed with blood. In addition to diarrhea, the malabsorption of water and electrolytes causes dehydration, weight loss (as observed in A.C.), and electrolyte disturbances.

A.C.'s rectal bleeding is secondary to colonic mucosal erosions and occurs in most patients with UC. Generally, bright red blood mixed in the stools indicates a colonic origin, whereas blood-streaked stools indicate an anal or rectal origin. The anemia associated with UC is generally secondary to this rectal bleeding. It presents as a hemorrhagic or iron-deficiency anemia, depending on the acuteness of the bleeding. Hemoglobin and hematocrit laboratory values often are decreased as in A.C.'s case. Chronic inflammatory disease–induced hypoalbuminemia is often exacerbated by malnutrition.

A.C.'s abdominal pain and cramping are caused by spasm of the irritated and inflamed colon. This abdominal pain is commonly associated with urgency to defecate. As illustrated by A.C., the pain is usually relieved with defecation, even though the stool volume may be small.

A.C.'s arthritis and elevated ALT are indicative of the extraintestinal manifestations that occur in IBD.[51] Her nonspecific symptoms (i.e., anorexia, fatigue, weight loss, anxiety, tachycardia) could become profound during an exacerbation of UC. Fever, leukocytosis, and increased ESR are also systemic manifestations of an inflammatory disease. Rehydration is important to assure fluid balance and maintain good renal function. Given her anemia, tachycardia, elevated ESR, and frequency of bloody stools, A.C.'s disease would be classified as severe.

CASE 24-1, QUESTION 2: How should A.C.'s diarrhea be managed?

Treatment of the diarrhea associated with UC is often difficult. In patients with mild-to-moderate disease, antidiarrheals, such as loperamide or diphenoxylate with atropine, may help minimize chronic diarrhea. Extreme caution must be used, however, especially in patients with severe disease because of the chance of inducing toxic megacolon, a life-threatening condition and medical emergency. For this reason, antidiarrheals are best avoided in patients with severe active disease, such as with A.C. Bulk-forming agents (i.e., psyllium) may be helpful for patients suffering from constipation caused by ulcerative proctitis.[52]

Remission Induction

CORTICOSTEROIDS

CASE 24-1, QUESTION 3: What agents can be used to induce disease remission in A.C.?

Corticosteroids are the most effective agents to induce remission of acute, severe exacerbations of UC. Clinical improvement or remission occurs in 45% to 90% of patients taking up to 60 mg/day of prednisone, with a recommended dose of 40 to 60 mg/day.[53] However, corticosteroids are not beneficial for maintaining remission. One strategy to minimize adverse effects of corticosteroid therapy is to taper them by 5 to 10 mg/week over 1 to 2 months after demonstrated improvement. Unfortunately, a subset of patients will experience a disease flare if the corticosteroid dosage is decreased or tapered too quickly. IV corticosteroids are an important option, especially in patients who have poor oral intake. Patients with active distal disease can be treated with hydrocortisone enemas; however, topical 5-ASA therapy is more efficacious. Biologic agents and cyclosporine may be considered for induction of remission in patients with fulminant disease or have failed other agents.[53] Given that A.C. is of childbearing age, a pregnancy test should be obtained and results taken into consideration when choosing current and future drug therapy, particularly if pregnant or breastfeeding[54] (see Chapter 49, Obstetric Drug therapy).

CASE 24-1, QUESTION 4: Methylprednisolone at a dosage of 40 mg IV every 6 hours is ordered. What are the treatment goals for A.C.?

The goal of parenteral corticosteroid therapy for A.C. is to achieve a rapid therapeutic response as measured by decreased frequency of stools, decreased pain, and decreased fever and heart rate. This goal may be attained with a high initial dose, followed by a gradual dosage reduction to minimize the development of corticosteroid adverse reactions.

Poorly nourished patients in whom oral intake is expected to be absent for more than 7 days should receive parenteral nutrition, and treatment should be continued until oral feeding is tolerated.[55] An adequate response is defined as resolution of fever and tachycardia, improved patient well-being, and less abdominal tenderness on palpation. Diarrhea is usually considered to be resolved with four or less bowel movements daily. Stools

---

are rarely formed at this stage, but macroscopic bleeding has stopped. Patients can then receive oral prednisone, a 5-ASA drug, and a light diet. If the patient does not respond within 72 hours of starting high-dose corticosteroids, infliximab or surgery may be indicated. Once A.C.'s symptoms are controlled, the goal should be to switch to oral corticosteroids and discharge her from the hospital.

Oral Administration

CASE 24-1, QUESTION 5: A.C. is responding well to methylprednisolone. She is afebrile, her abdominal pain is reduced (to a score of 4 on a 1–10 scale), and her diarrhea is decreasing. When is the oral route of corticosteroid administration indicated in UC? What are the most appropriate dosages?

Oral corticosteroids are effective for the initial treatment of mild-to-moderate acute UC.[25] In addition, they should be substituted for parenteral corticosteroids once a satisfactory initial response of more severe exacerbations has been achieved. Prednisone of 40 mg/day was significantly more efficacious than 20 mg/day in controlling ambulatory patients with moderately severe acute UC, but prednisone doses of 60 mg/day had no additional therapeutic value, while causing more adverse effects.[17] In addition, a single 40-mg morning dose of prednisone was as effective as and more convenient than an equivalent divided dose (10 mg 4 times a day [QID]). Therefore, the initial dose of corticosteroid for a patient with moderately severe acute UC is 40 mg of prednisone or its equivalent administered once daily in the morning.

Although corticosteroids are effective for inducing remission in many cases of IBD, up to 50% of patients may not respond (steroid resistant) or will be steroid-dependent at 1 year.[24] Additionally, rates of mucosal healing with these drugs are less than those with other modalities.[56] This combined with the significant adverse effects of corticosteroids (e.g., hyperglycemia, osteoporosis) argue against their long-term use in IBD, as reflected in current practice guidelines.[16,17]

Topical Administration

CASE 24-1, QUESTION 6: What if A.C.'s UC was limited to the distal colon or rectum? Would topical corticosteroids be indicated? When should other topical agents be considered for A.C.?

Topically administered 5-ASA and corticosteroids, in the form of suppositories, foams, and retention enemas, are effective in the management of acute, mild-to-moderate UC that is limited to the distal colon and rectum.[22]

The desired outcome for medications administered via this topical route is to provide a higher concentration of drug to the diseased mucosal area, exerting a local anti-inflammatory effect, while minimizing systemic side effects. Unfortunately, variable but significant systemic absorption (up to 90%) and adrenal suppression occur from the topical administration of corticosteroid to the rectum and distal colon.[57] Therefore, the beneficial effects produced by topical use of these agents may accrue from both systemic and local effects. The relatively low incidence of corticosteroid side effects associated with topical administration may be related to both the low doses and the infrequent administration (daily to twice daily) needed to control mild acute UC.

5-ASA suppositories and enemas are preferred over topical corticosteroids for the treatment of distal UC and proctitis because they produce higher remission rates in proctitis and effectively maintain remission of distal UC.[57] For distal UC, therapy is initiated with a nightly enema (4 g of mesalamine), and the response should be evaluated in 3 to 4 weeks. For mild acute proctitis, administering one suppository of 5-ASA twice daily for 3 to 6 weeks is generally sufficient to induce disease remission. Improvement should be seen in 2 to 3 weeks, and therapy should be maintained until complete remission is achieved. If remission is attained, therapy can then be tapered to one suppository or enema, 2 to 3 times weekly. Therapy with oral plus topical mesalamine showed greater efficacy than either alone in achieving remission of distal UC or proctitis.[22]

Adverse Effects

CASE 24-1, QUESTION 7: What particular corticosteroid adverse effects should the clinician monitor in A.C.?

Corticosteroid side effects and precautions for use often limit the therapeutic effectiveness of these agents and should never be overlooked.[24] Certain glucocorticoid adverse effects are of particular importance in patients with IBD in that they may mimic, mask, or intensify symptoms and complications of this disease. For example, the symptoms of peritonitis, one of the major complications of intestinal perforation, may be masked by corticosteroids. Other deleterious effects of corticosteroids include hyperglycemia, avascular necrosis, cataract formation, and central nervous system effects, including mood disorders, insomnia, psychoses, and euphoria.

Patients with IBD are at risk for decreased bone mineral density, which is exacerbated by prolonged use of corticosteroids.[58,59] This is an often-overlooked side effect of these drugs. One study suggested that even budesonide, with its low overall bioavailability, causes this adverse effect.[60] Thus, calcium, vitamin D supplements, and possibly bisphosphonates are recommended to minimize metabolic demineralization in all IBD patients taking corticosteroids for longer than 3 months. Given the patient's family history (mother with osteoporosis) and her high risk of bone loss, alendronate 35 mg weekly with 1,500 mg daily of calcium and 800 international units of vitamin D intake should be initiated.

SULFASALAZINE AND 5-AMINOSALICYLIC ACID

CASE 24-1, QUESTION 8: A.C. is still responding well to oral prednisone; however, her blood glucose concentrations have ranged from 226 to 445 mg/dL (normal, 70–110 mg/dL). Her physician would like to try another modality for active treatment. What other drugs could be used for remission induction?

Previously, sulfasalazine was considered the drug of choice in UC exacerbation because of its demonstrated efficacy and reduced toxicity when compared with corticosteroids. However, controlled trials have shown that corticosteroids may act more promptly than sulfasalazine alone for severe acute UC.[4] Sulfasalazine use has declined significantly since the availability of better-tolerated 5-ASA formulations.[21] Additionally, as in the case of A.C., patients with a sulfa allergy should avoid sulfasalazine. Clinical improvement or remission of mild-to-moderate UC can be attained in 40% to 74% of patients treated with oral 5-ASA in doses ranging from 1.5 to 4.8 g/day with further improved response at dosages greater than 2 g/day.[61,62] In summary, oral 5-ASA compounds are considered first-line therapy for mild-to-moderate exacerbations of UC, with systemic corticosteroids reserved for more severe active UC or refractory disease. Because A.C. has improved symptomatically and is suffering significant adverse effects from corticosteroid treatment, switching to oral mesalamine is a reasonable option at this time.

Remission Maintenance

MESALAMINE

CASE 24-1, QUESTION 9: A.C. feels much better and claims to be "back to normal." Her abdominal pain is gone, and she currently has two formed, non-bloody stools daily. Most of her laboratory parameters have returned to normal (ESR, 19 mm/hour; blood glucose, 95 mg/dL; WBC, 8,300/μL). She is currently taking mesalamine 800 mg PO TID. What drug regimen should be used to maintain disease remission in A.C.?

5-ASA agents significantly reduce the incidence of relapse in UC patients who are in remission.[17,19] At 12 months, 65% to 70% of patients remain relatively symptom-free compared with placebo.[63] As discussed previously, the anatomic site of disease is an important consideration in the selection of a 5-ASA preparation.[20,21] Data also suggest that, if tolerated, higher doses have higher rates of treatment success. In contrast, oral and topical corticosteroids do not prevent relapse of UC once remission has occurred.

On the basis of this information, A.C.'s mesalamine should be titrated to a total dose of 4.8 g in divided doses. If she experiences a relapse, a course of oral corticosteroids may be needed to re-achieve remission. Prophylactic therapy should be continued indefinitely unless intolerable adverse effects develop. This is especially true in light of data that suggest that long-term mesalamine may be chemoprotective against colon cancer.[63]

Adverse Effects

CASE 24-1, QUESTION 10: A.C.'s mesalamine has been increased to 1,200 mg TID for UC maintenance therapy. Several days after starting this higher dose of mesalamine, A.C. experienced anorexia, nausea, and epigastric pain. What is the possible cause of A.C.'s symptoms? How can they be minimized?

A.C. appears to be experiencing adverse effects of mesalamine. Although usually better tolerated than sulfasalazine, unwanted adverse effects occur in 10% to 45% of patients. Most 5-ASA adverse reactions are dose related and tend to occur early in the course of therapy.

Dose-related 5-ASA adverse effects can be minimized by initiating the patient on a low dosage (1–2 g/day) and gradually increasing the amount to tolerated therapeutic doses.[62] If dose-related reactions do occur, the drug should be discontinued until the symptoms subside, then it may be reinstituted at a lower dosage. A.C.'s symptoms are probably dose-related adverse reactions to mesalamine. The dosage should be decreased, or the drug temporarily withheld. If tolerated, the dosage can be increased slowly as necessary, or she can be switched to another agent to maintain disease remission, such as an immunomodulator. An algorithm depicting treatment for UC is shown in Figure 24-1.

IMMUNOSUPPRESSIVE AND BIOLOGICAL AGENTS

CASE 24-1, QUESTION 11: A.C.'s dose of mesalamine was decreased to 800 mg TID. After 2 weeks, A.C. continued to have nausea, diarrhea, and headache severe enough to cause her to miss classes and call in sick from her part-time job. Objectively, she has lost 5 kg (now 46 kg) in the last week as a result of anorexia and nausea. What alternative therapies should be considered at this point?

The results of several trials suggest AZA and 6-MP are appropriate alternatives for patients with active UC that have not responded to systemic steroids, although their actual level of effectiveness is debated.[64,65] These drugs are also used to maintain remission, although they are probably used more in CD than UC for this purpose (see Case 24-2, Question 3).

Infliximab, adalimumab, and vedolizumab are approved in the United States for moderate-to-severe UC (both for induction therapy and for maintenance of remission). Because of significant costs and adverse effects, they should be reserved for patients with refractory disease.

Figure 24-1 Treatment algorithm for ulcerative colitis. Pancolitis refers to extensive ulcerative colitis. 5-ASA, mesalamine products, including mesalamine (e.g., Asacol, Pentasa, Rowasa), olsalazine, and balsalazide (see text for selection guidelines); IV, intravenous; 6-MP, 6-mercaptopurine; UC, ulcerative colitis. [a]For UC adalimumab is an alternative option to infliximab. (Source: Bernstein CN et al. World Gastroenterology Organization Practice Guidelines for the diagnosis and management of IBD in 2010. Inflamm Bowel Dis. 2010;16:112; Carter MJ et al. Guidelines for the management of inflammatory bowel disease in adults. Gut. 2004;53(Suppl 5):V1; Kornbluth A et al. Ulcerative colitis practice guidelines in adults: American College of Gastroenterology, Practice Parameters Committee. Am J Gastroenterol. 2010;105:501.)

Cyclosporine (CSA) has also been used to treat active UC. In one retrospective review, IV CSA had a roughly 50% response rate even 2 years after acute therapy.[65] Many drug interactions and adverse effects are associated with CSA. Hypertension, gingival hyperplasia, hypertrichosis, paresthesias, tremors, headaches, electrolyte disturbances, and nephrotoxicity are common. In A.C., a reasonable choice would be AZA 115 mg (approximately 2.5 mg/kg/day). Monthly monitoring of WBC counts and liver function testing as well as periodic assessment for any signs and symptoms of pancreatitis would be appropriate.[66]

Vaccinations in the IBD Patient

CASE 24-1, QUESTION 12: One year has passed since A.C. last had an acute attack of UC. She has been taking AZA 2.5 mg/kg/day. Today she presented to her primary health care provider for her annual physical examination. She asked about receiving the yearly influenza vaccination as well as the pneumococcal vaccination she has been reading about online. Her primary care provider is unsure whether A.C. is a candidate for either vaccination. Should A.C. receive both vaccinations? What vaccinations, if any, is A.C. a candidate for?

Immunomodulators and biologic drugs are the mainstay of IBD treatment. However, one of the most important adverse effects are infectious complications. As mentioned above, serious and sometimes fatal infections have been reported with drugs such as AZA and infliximab.[42] Some of these infections are preventable with immunizations.[67] Unfortunately, data exist that immunization strategies are significantly underutilized in the IBD population.[68] Guidelines recommend that standard immunization schedules (see Chapter 64, Vaccinations) be adhered to; that serologic testing for varicella be performed on IBD patients without a clear history of chickenpox, and if negative, such patients should be vaccinated against this virus; and that live virus vaccinations should be avoided in patients, such as A.C., who are receiving AZA.[68] Specifically, concerning A.C., she should receive the seasonal influenza vaccine as well as the 23-valent pneumococcal polysaccharide vaccine and hepatitis B vaccine. Many patients with IBD would also be candidates for the human papilloma virus vaccine, and given the increased incidence of abnormal Papanicolaou tests in this population, this would be a reasonable strategy.[69]

CROHN'S DISEASE

Pathophysiology and Clinical Presentation

CASE 24-2

QUESTION 1: C.J., a 30-year-old man, was well until 18 days ago when he experienced crampy right lower quadrant abdominal pain associated with an increased frequency of semiformed stools (4–5/day). The pain was episodic at first, exacerbated by meals, and somewhat relieved by defecation. During this time, C.J. experienced anorexia and a 10-pound weight loss. He denied any change in vision, joint pain, or the appearance of skin rashes. He has not traveled outside the United States or taken antibiotics recently.

Physical examination is essentially normal, except for soft, loose, watery stools that are streaked with fat and positive for occult blood. The abdomen is tender on palpation of the right lower quadrant. Vital signs include a temperature of 37.8°C, pulse of 100 beats/minute, and blood pressure of 135/75 mm Hg. He is 180 cm and weighs 80 kg. Pertinent laboratory values include the following:

Hct, 28%
Hgb, 9 g/dL
WBC count, 14.0×10^9/L
ESR, 60 mm/hour

Results of sigmoidoscopy and rectal biopsy are negative. Stool cultures and toxin studies for C. difficile are negative, as is the examination for signs of trophozoites. A barium enema shows an edematous ileocecal valve and a terminal ileum that has a nodular irregularity of the mucosa. Follow-up colonoscopy reveals a cobblestone-appearing terminal ileum with areas of normal tissue separated by diseased mucosa. Which of C.J.'s signs, symptoms, and laboratory data are consistent with CD? Describe the pathophysiological basis for C.J.'s clinical presentation.

C.J., like most patients with CD, presents with the classic symptom triad of abdominal pain, diarrhea, and weight loss.[11] His most frequent symptom is right lower quadrant abdominal pain, which is secondary to an indolent inflammatory process in the ileocecal area. Diarrhea is also a characteristic symptom; however, in contrast to UC, the stools are usually partly formed, and gross blood is generally not visible. If the disease is limited to the colon, the diarrhea may be of the same quality and quantity as that associated with UC. If the disease is limited to the ileum, as it appears to be with C.J., the diarrhea is generally moderate, with four to six stools daily. If ileal involvement is significant, bile salt malabsorption may occur, resulting in steatorrhea. Weight loss may be pronounced in patients with long-standing CD because of anorexia and malabsorption. Additionally, vitamin deficiencies, including vitamin B_{12} and vitamin D, are more common in CD patients than control subjects.[70]

Rectal bleeding often occurs in patients with CD, particularly those with colonic involvement, although it is not as common as that associated with UC. Slow blood loss may occur in patients with disease limited to the small intestine, which may cause occult blood-positive feces and, eventually, anemia, as illustrated by C.J. Massive hemorrhage is usually a late complication of CD and is generally caused by transmural ulceration and subsequent erosion into a major blood vessel.

C.J.'s leukocytosis and increased ESR demonstrate that, like UC, CD is a systemic disease. Extraintestinal manifestations such as arthritis, liver disease, and skin rash occur in CD with the same frequency as UC. However, some types of extraintestinal disease appear to be more common in UC (e.g., primary biliary cirrhosis) than CD (e.g., pyoderma gangrenosum).[71]

Most patients with CD have recurrent, symptomatic episodes of pain and diarrhea with gradual progression of their disease to shorter and shorter asymptomatic periods. Although the clinical course is generally progressive, 10% of patients will remain essentially asymptomatic after a few acute episodes.[72] Other patients may only manifest a slight fever for years until a late complication of the disease, such as fistula formation, develops. Alternatively, CD may be rapidly progressive.

Remission Induction

CASE 24-2, QUESTION 2: What agents can be used to induce a remission of C.J.'s CD?

Because the clinical course of CD varies among patients, the management of this disease must be individualized. The anatomic location of the disease is also an important determinant

---

of therapy. Most investigations evaluating the treatment of acute symptomatic CD have ignored this factor and are therefore difficult to assess or compare.

CORTICOSTEROIDS

Corticosteroids are the most widely used therapeutic agents for the treatment of active, symptomatic CD.[16,24] A systematic review of the literature confirms that steroids have a valuable role in remission induction.[56] Landmark studies have demonstrated that approximately 60% to 80% of patients with active CD will respond to a course of corticosteroids.[24] These agents seem to be particularly effective in ileal and ileocolonic disease and can induce remission in even moderate-to-severe CD. Budesonide is also recommended in current CD guidelines for active mild-to-moderate ileocolonic CD.[16]

5-AMINOSALICYLIC ACID

Although previously used extensively for mild-to-moderate CD, current trial data and expert opinion have limited the role of 5-ASA drugs to mild active colonic CD. A large meta-analysis comparing 5-ASA (Pentasa) versus placebo found a small and probably clinically insignificant treatment benefit.[73]

OTHER INDUCTION AGENTS

The immunomodulators AZA, 6-MP, and MTX have an onset of action of weeks to months and are not usually appropriate monotherapy for treatment of a CD flare. Infliximab is effective for both active and quiescent disease.[74] It can be used alone owing to its rapid onset. A recent landmark study found that early aggressive use of infliximab, with or without AZA, was associated with both corticosteroid-free clinical remission and mucosal healing in patients with moderate-to-severe CD.[31,74] Newer agents have been approved. Clinical studies have suggested a roughly equivalent symptom response between adalimumab and infliximab, and because the former drug is also a potent TNF-α blocker, similar safety concerns and adverse effects have been shown between the two agents.[40] Efficacy has also been demonstrated in the treatment of fistulating Crohn's disease.[75] One potential advantage of adalimumab is its ability to be self-administered subcutaneously by patients. Certolizumab contains only the antibody receptor for TNF-α bound to polyethylene glycol to increase its duration in the body. Currently, it is only approved for both inducing and maintaining remission in CD.[76] A prefilled syringe is now available for self-administration. Infection and other adverse effects have been reported in clinical trials that are similar to other TNF-α blockers. Two randomized controlled trials have found that natalizumab may be beneficial for induction and maintenance of remission of moderate-to-severe CD in a small subset of patients, but at the increased risk of developing progressive multifocal leukoencephalopathy (PML), a potentially fatal adverse effect.[77] Thus, natalizumab should be reserved as a last-line agent. Furthermore, patients are required to be enrolled in a mandatory patient registry program (TOUCH) to receive the drug and should avoid concomitant immunosuppressive therapies.[78] In 2014, vedolizumab was approved for inducing and maintaining remission of moderate-to-severe UC and CD in patients who have failed TNF-α therapy. There were no cases of PML observed in clinical trials and the medication does not currently require a restricted distribution program.[79]

Certainly, the added expense and risk of using biologics earlier in this population needs to be weighed against the possibility of longer periods of remission and avoidance of surgery. An additional concern is reports of hepatosplenic T-cell lymphoma in young men receiving either AZA or 6-MP with or without concomitant infliximab, which is usually fatal.[80] An algorithm for the treatment of CD is depicted in Figure 24-2.

Remission Maintenance

CASE 24-2, QUESTION 3: After 4 weeks of prednisone 40 mg daily, C.J. experienced fewer symptoms of CD; he has one to two well-formed stools a day, increased appetite and weight, decreased abdominal pain and tenderness, and normal body temperatures. Should prednisone be discontinued? What agents are effective in maintaining remission of symptoms in patients with CD?

CORTICOSTEROIDS

Once prednisone has induced remission of active symptomatic CD, attempts should be made to taper the drug.[16] The tapering schedule is usually fairly slow (typically, a dose reduction of 5%–10%/week), taking several weeks to months to complete. Several studies have demonstrated that corticosteroids are ineffective in maintaining remission in CD, and many patients continue to have active disease while receiving therapy. However, a significant subset of patients (25%) with CD requires chronic administration of corticosteroids to prevent recurrence of symptoms (termed steroid-dependent CD).[81] Given the poor long-term adverse effect profile of steroids, many clinicians attempt treatment with other modalities to maintain remission.

6-MERCAPTOPURINE OR AZATHIOPRINE

Both 6-MP and AZA have a major role in maintenance treatment of CD, particularly as a steroid-sparing strategy. Recent guidelines recommend the use of 6-MP and AZA in most relapsing cases of CD, regardless of anatomic site, and for both severe and steroid-dependent disease. Provided patients are appropriately monitored, these agents are safe with a favorable risk–benefit ratio. Both 6-MP and AZA are the first-line immunomodulators used in CD. Should these agents be ineffective or not tolerated, either MTX or infliximab can be used to maintain remission.[15] The top-down strategy of starting TNF blockers earlier in the course of disease is currently under debate.[81–83] Recent findings have prompted experts to increasingly advocate initial therapy with biologic drugs in high-risk patients with moderate-to-severe CD (“top-down” therapy) rather than initiating after other agents have failed.[3,31,74] Some experts believe that infliximab should be used earlier in the course of relapsing disease, especially in patients with fistulae.[82]

In summary, C.J.'s prednisone should be tapered as suggested previously and then discontinued if possible. As the tapering regimen is begun, C.J. should start 6-MP 120 mg (approximately 1.5 mg/kg/day) or AZA 200 mg (approximately 2.5 mg/kg/day). This is because of the long onset of effect for the latter drugs (usually 3–6 months). C.J.'s WBC counts should be monitored regularly, and he should be counseled regarding the signs and symptoms of severe infection (e.g., fever, sore throat, or chills) and pancreatitis (e.g., severe epigastric pain and nausea).

Adverse Effects

CASE 24-2, QUESTION 4: Six weeks after starting to taper C.J.'s prednisone dosage (currently, 10 mg/day) and the initiation of AZA, he returns to the clinic for routine laboratory monitoring. His WBC count is 1,800/µL with an absolute neutrophil count of 1,100/µL. He is afebrile and without complaint. His physical examination is negative for any sign of infection. Why is C.J. experiencing leukopenia? What is the treatment for this side effect?

6-MERCAPTOPURINE AND AZATHIOPRINE MONITORING

AZA is a prodrug that is converted to the active moiety, 6-MP, in the liver. 6-MP is then metabolized by xanthine oxidase, hypoxanthine-guanine phosphoribosyltransferase, or thiopurine-S-methyltransferase (TPMT). Genetic polymorphism determines the extent of TPMT activity. In approximately 90% of whites, TPMT activity is considered high, but the remainder of the population has either intermediate or low TPMT activity.[83,84] These patients are predisposed to 6-MP or AZA myelosuppression because diminished TPMT activity leads to the metabolism of these compounds being shunted to the other enzymatic pathways. Accumulation of the 6-thioguanine byproducts is correlated with leukopenia. Pharmacogenomic testing to assess TPMT activity has been developed and found to be effective in guiding therapy with AZA or 6-MP, while minimizing the incidence of bone marrow suppression.[85] The CD guidelines note that no randomized controlled trials have compared pharmacogenomic guided dosing to usual care dosing in patients receiving AZA or 6-MP. However, the US Food and Drug Administration recommends such testing before initiating these medications.[85] Additionally, several retrospective studies have assessed the clinical utility of measuring AZA and 6-MP metabolites such as 6-thioguanine and 6-methylmercaptopurine.[86] Although some experts have used these data to suggest a therapeutic level for these metabolites (e.g., 6-thioguanine levels of 250–400 pmol/8 × 10^8 red blood cells have been considered optimal), the CD guidelines do not recommend their routine use.[16] The optimal role for these tests remains to be fully determined, and data in this area are rapidly evolving.

Figure 24-2 Treatment algorithm for Crohn's disease. KEY: CD, Crohn's disease; 5-ASA, aminosalicylate; 6MP, 6-mercaptopurine; MTX, methotrexate; [a]For nonfistulizing Crohn's disease adalimumab or certolizumab are alternative options to infliximab.

In patients who have experienced neutropenia from AZA therapy, as C.J. has, the primary treatment is to discontinue AZA. In most cases, the WBC count will normalize over the course of several days to weeks. In extreme cases, the use of granulocyte colony-stimulating factor may be considered. C.J. should be monitored for signs and symptoms of infection, and the AZA should be withheld. Frequent, conceivably daily, WBC determinations should be made until the count is greater than 3,000/μL.

OTHER AGENTS

CASE 24-2, QUESTION 5: C.J.'s leukocyte count returned to normal after 2 weeks. Unfortunately, he experienced a flare of his CD symptoms, specifically, an increase in diarrhea and abdominal pain that C.J. has noted during the past 5 days. What other agents should be considered to maintain remission in C.J.?

A number of other immunosuppressive drugs have been examined in CD. MTX produces and maintains remission in patients with refractory disease. Clinical improvement or reduction in corticosteroid dosages have been observed with 15 mg/week oral MTX or 25 mg/week of intramuscular or subcutaneous MTX in roughly 40% of patients who had active bowel disease.[87,88] In clinical studies, GI toxicity was the most common reason for discontinuing treatment, but neutropenia and liver enzyme elevations were also reported.[89] Current guidelines recommend reserving MTX for patients who have failed or are intolerant of 6-MP or AZA. Some experts consider MTX to be inferior to 6-MP or AZA in CD, but no comparison studies have been published to date. Given an apparent therapeutic failure with AZA, a reasonable approach would be a short course of corticosteroids (prednisone 40 mg daily with a taper for 6–8 weeks) and MTX 25 mg weekly. Folic acid 1 mg daily should be initiated in patients started with the MTX. MTX use may result in a depletion of folate stores because of dihydrofolate reductase inhibition. Alternatively, biologic therapy could also be considered.

Metronidazole

CASE 24-2, QUESTION 6: C.J. has developed an enterocutaneous fistula with his latest disease exacerbation, and nothing is helping him achieve remission. What alternatives are appropriate for C.J.?

Recent guidelines recommend that antibiotics have little role in the maintenance of remission in CD, but they may be helpful in fistulizing disease or in patients with abscesses. Taste disturbances and peripheral neuropathy are the most commonly reported adverse effects associated with metronidazole treatment.

Infliximab

Infliximab is now firmly established as an important therapy in the treatment of CD, especially fistulizing disease. However, a number of concerns regarding this agent must be discussed with the patient before initiation of therapy. It is an expensive therapy (approximately $15,000/year), although it may be cost effective in CD.[90] Fistulizing disease seems to respond particularly well to infliximab, and its use may avert the need for surgery.[89] Acute and delayed hypersensitivity reactions can occur and are occasionally life threatening.[21] Some clinicians premedicate patients with a combination of diphenhydramine, acetaminophen, or corticosteroids before an infusion; however, the most effective strategy to avoid a serious reaction is to regularly monitor vital signs during infliximab infusion and slow the rate or stop the infusion if any symptoms develop. The majority of reactions consist of headache, flushing, itching, and dizziness, with anaphylactic reactions rarely occurring. Also of concern is the development of human antichimeric antibodies in some patients receiving infliximab, which may lead to either loss of response or immunologic adverse reactions.

Infliximab should be avoided in patients who have a serious active infection. Because of reports that infliximab treatment may reactivate tuberculosis, all patients considered for treatment must receive a tuberculin skin test to rule out the disease (see Chapter 68, Tuberculosis). If this test is negative and because C.J. does not appear to have any other contraindications, he would seem to be an appropriate candidate for infliximab. If latent tuberculosis is found, antitubercular treatment must be initiated before infliximab can be considered since patients with treated latent tuberculosis still have an increased risk of active disease.[91,92] In addition, screening for hepatitis B (and probably hepatitis C) is reasonable owing to the number of cases describing reactivation of these viral infections.[66] Current data concerning a link between TNF-α blockers use and malignancy are conflicting.[93] To date, the balance of data suggests a small but real risk of developing lymphoma in CD patients using TNF-α blockers, but despite this, its use is associated with an increase in quality-adjusted years of life.[94] Another problem commonly faced by clinicians and patients is loss of effectiveness in patients receiving TNF-α blockers. This may occur months or years after initiation of therapy. Common strategies to regain response may include increasing the dose of infliximab to 10 mg/kg per dose or switching to another TNF-α blocker. The success of these strategies is variable, and often comes with significantly increased treatment costs.[40] A recent paper has shed light on the possible causes of this loss of efficacy.[41] In 155 patients receiving infliximab, who had declining response to the drug, both trough serum infliximab levels and human anticlonal antibodies (HACA) were measured. The authors found that in patients with subtherapeutic trough infliximab levels, increasing the dose of the drug was a successful strategy to regain response, whereas those patients who were HACA-positive benefited more from changing to another TNF-α blocker. Such laboratory markers may have the potential to be routinely used to assess the effectiveness of infliximab, but more data on this issue are needed to make such a recommendation.

Surgery in Crohn’s Disease

CASE 24-2, QUESTION 7: C.J. was initiated on infliximab 400 mg IV every 8 weeks, and it was successful at keeping him symptom free. However, after 2 years of remission, C.J. is hospitalized for an acute exacerbation of right lower quadrant pain associated with abdominal distension, lack of bowel movements, and vomiting during the past 24 hours. Radiographic studies indicate partial small bowel obstruction at the terminal ileum. Is surgery indicated at this time?

Because medical therapy of CD is often inadequate, 78% of patients with this disease will require surgery within 20 years of symptom onset.[4] In contrast to UC, surgical removal of the involved bowel in CD is not a definitive form of therapy. CD can recur even after extensive resections.[72] Various investigations have determined that cumulative recurrence rates after surgery for this disease are as high as 80%, depending on the surgical procedure and disease location. Therefore, multiple operations and their attendant risks are often necessary during the life of the CD patient. Depending on the amount and site of the bowel removed during surgery, specific malabsorption syndromes can occur (e.g., vitamin B_{12} malabsorption with removal of the terminal ileum). If an ileostomy is part of the surgical procedure, the patient will have to undergo significant psychological adjustments. Therefore, surgery is indicated only for specific complications that are unresponsive to medical therapy, and it should be avoided if possible.

IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is one of the most common chronic, relapsing, but benign disorders causing patients to seek medical treatment. It exerts a significant economic burden and is responsible for considerable morbidity in Western countries. Until recently, little was understood about the pathophysiology or etiology of this disorder. Indeed, some controversy exists today as to whether IBS is a distinct syndrome or a grouping of several chronic GI disorders. Still, investigators have made strides in understanding IBS, particularly the role of the enteric nervous system in the etiology of this disorder. As a result, new pharmacotherapeutic options are emerging for patients experiencing this often bewildering condition.

IBS can be defined as "a functional bowel disorder characterized by abdominal pain associated with a change of bowel habit."[95] The incidence of IBS has been reported to be 3% to 20% in Western countries.[96] It is the most common disorder seen by gastroenterologists and is commonly seen by primary-care clinicians as well.[97] Prevalence rates are dependent on IBS diagnostic criteria, which have varied over the years. A female sex predominance of about 3:1 is evident in most epidemiologic studies of IBS.[96] Some studies have demonstrated a white predominance in IBS, whereas other studies have found no such association. Many patients with IBS never seek medical attention, and those who do tend to see their physician frequently.[98]

Many of these patients also have other functional disorders, such as fibromyalgia and interstitial cystitis; and psychiatric disorders, such as major depression and generalized anxiety disorder. It is estimated that IBS accounts for $33 billion in direct and indirect costs in the United States annually.[99]

Pathophysiology

Although knowledge of the cause of IBS remains incomplete, several theories have emerged to explain the underlying pathophysiology of this disorder. Previously, the primary cause of IBS was believed to be psychiatric or psychosomatic. This picture was at least partially validated by the finding that many IBS patients had psychiatric comorbidities. Today, it is believed that factors such as psychological stress may exacerbate the disease, but they are not the cause of IBS.[100] It has long been known that IBS patients tend to exhibit visceral hypersensitivity to colonic stimulation or manipulation. Although concomitant anxiety and hypervigilance undoubtedly played a role in such observations, it is now believed that the reaction to visceral stimuli in these patients results in the perception of abdominal pain, whereas patients without IBS would have no symptoms. The etiology of this hypersensitivity is the focus of intense research efforts. Theories have emerged suggesting that the activation of silent gut nociceptors owing to ischemia or infection may lead to increased abdominal pain in IBS.[100] Other experts propose that an increase in the excitability of neurons in the dorsal horn of the spinal cord lead to gut hyperalgesia. An abnormality in the processing of ascending signals from the dorsal horn may be responsible for a lower pain threshold in IBS patients. Similarly, findings suggest that neurotransmitter abnormalities may cause the symptoms of IBS. Of particular interest is the role of serotonin (5-HT) in the etiology of this disorder. Greater than 95% of the body's 5-HT is located in the GI tract and is stored in many cells, such as enterochromaffin cells, neurons, and smooth muscle cells. When released, this 5-HT can trigger both GI smooth muscle contraction and relaxation, as well as mediate GI sensory function.[101] Different 5-HT receptor subtypes may be responsible for these differing actions. A study examining rectal biopsy specimens in patients with IBS found defects in 5-HT signaling, supporting the theory of neurotransmitter abnormalities.[102] The primary 5-HT subtypes in the GI tract are 5-HT$_3$ and 5-HT$_4$. Some data suggest that IBS patients may have higher levels of 5-HT in the colon compared with control subjects.[103] Thus, these receptors have become the target of pharmacotherapeutic manipulation for IBS.

Another proposed pathological mechanism of IBS is altered colonic motility. Diarrhea, constipation, and abdominal bloating are common features of IBS. Patients with IBS are often categorized as having either IBS with diarrhea (IBS-D) or IBS with constipation (IBS-C).[95] About one-half of patients with IBS report increased symptoms postprandially, and patients with IBS-D have been shown to have an exaggerated response to cholecystokinin after eating, leading to increased colonic propulsions.[104] However, patients with IBS-C tend to have fewer colonic propulsions postprandially. Patients in whom bloating is the primary symptom of IBS may have gas production from poor fermentation of carbohydrates.[105] This has led investigators to search for a link between bacterial overgrowth of the small bowel (leading to an increase of gas production and pain and bloating symptoms) and IBS.

Etiology

The pathogenesis of IBS is poorly understood, although consensus theories are emerging. Some investigators believe that inflammation of the GI mucosa associated with infection may be the triggering factor that results in IBS.[98] The fact that symptoms associated with IBS can appear in up to 30% of patients who had an episode of bacterial gastroenteritis in the recent past lend credence to an infectious etiology.[106] Recent studies have also determined that a percentage of patients diagnosed with IBS may in fact have small intestinal bacterial overgrowth.[107] Diagnosis of the latter disorder is particularly important as treatment may involve a simple course of antibacterials. Also controversial is the possible association of a history of physical or sexual abuse and the development of IBS.[108] Most IBS patients under emotional or psychological stress will report an exacerbation of their symptoms, but this is not surprising considering that such stressors affect non-IBS patients' GI function as well.[109] Familial clustering of IBS patients suggests that both genetics and formative environments may play a role in the pathogenesis of this disorder.[110] Finally, food intolerances (e.g., lactose intolerance) may be misdiagnosed as IBS.

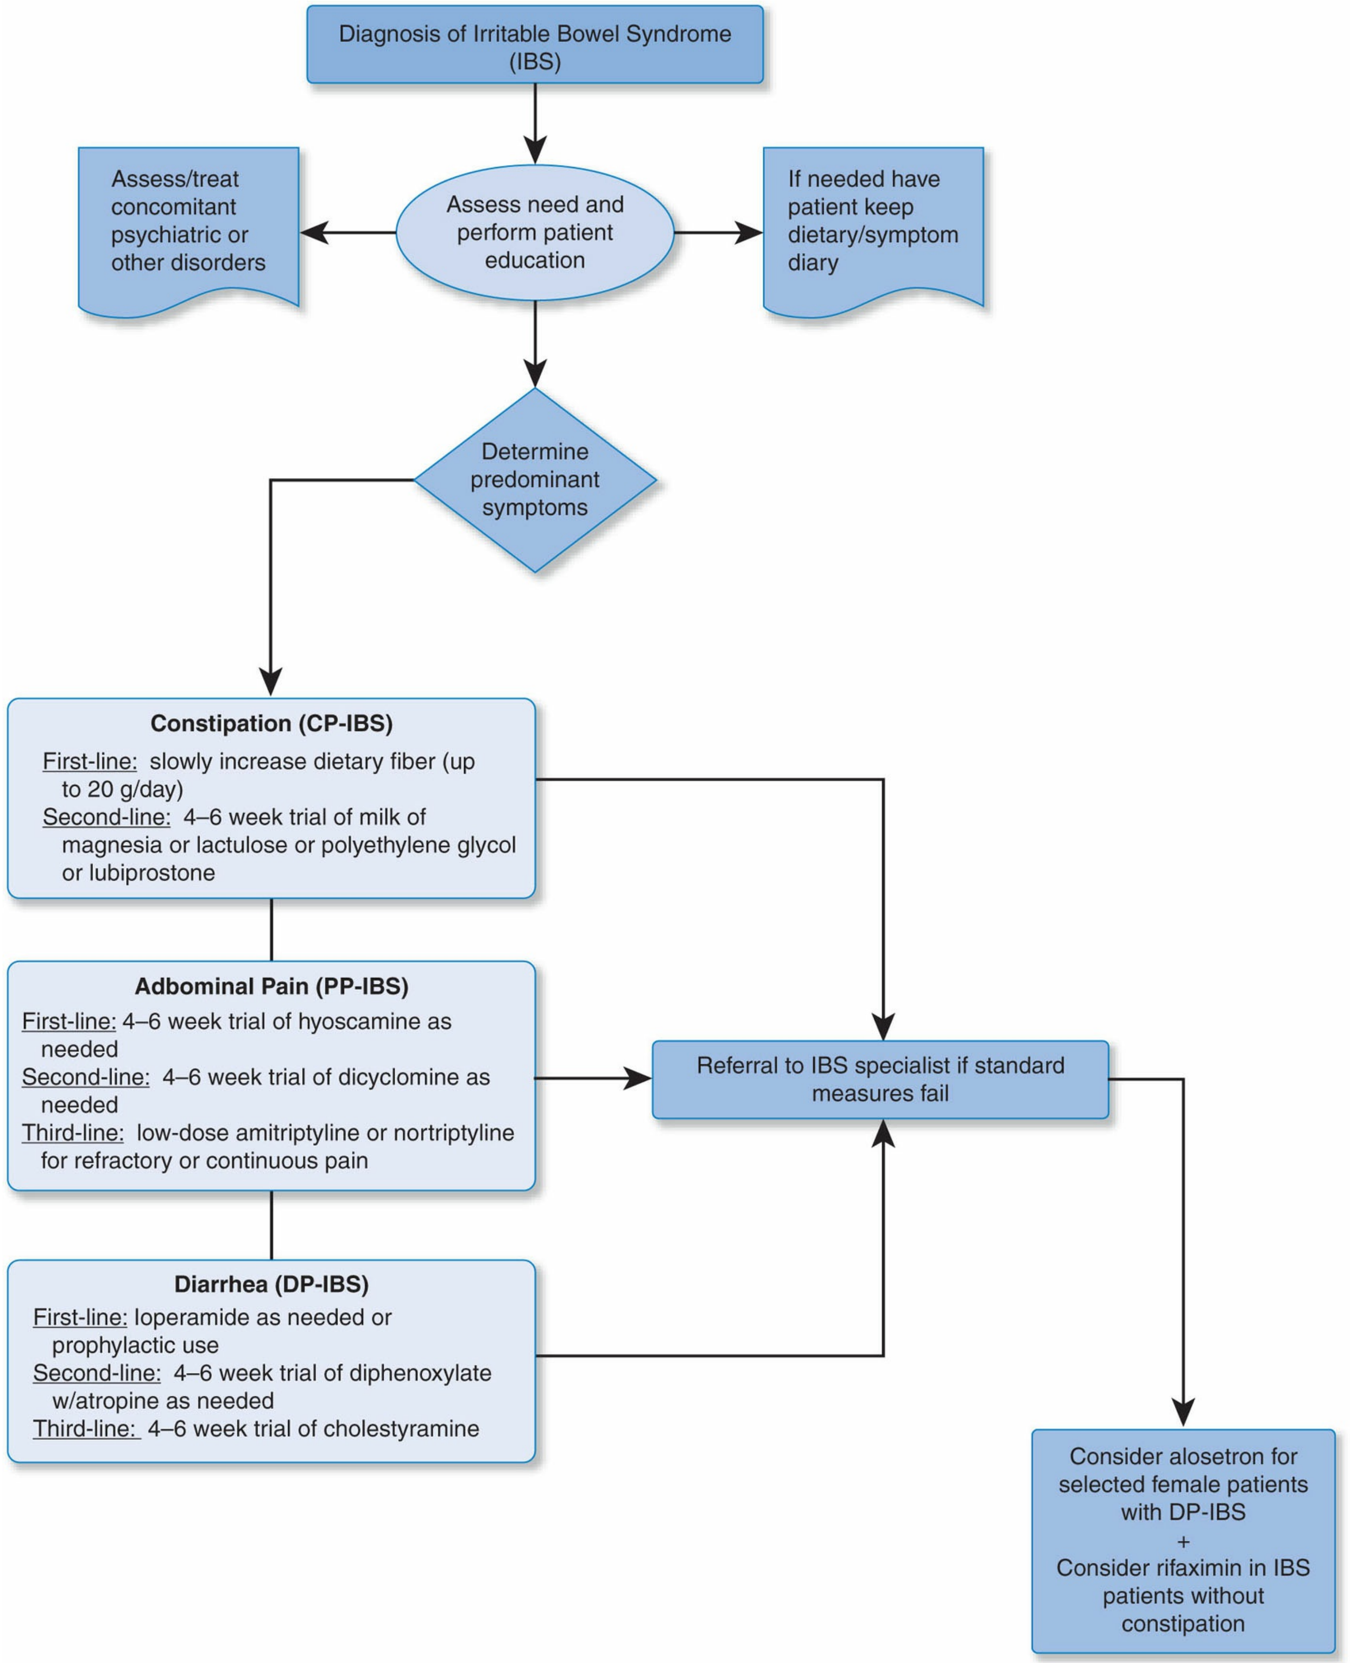
Diagnosis

One of the more challenging and frustrating aspects of IBS is its lack of biochemical or physical markers that are pathognomonic for the disorder. This lack of "objective" criteria for diagnosis can propagate the notion that IBS is a psychological or psychosomatic disorder. Many patients express frustration with the traditional medical establishment and individual providers.[111] Patients and providers often want expensive laboratory or imaging tests to rule out other diseases; however, guidelines suggest that extensive testing in IBS patients is usually unnecessary provided that patients are younger than 50 years and do not present with any alarm symptoms. Alarm symptoms include:

- Abdominal pain and cramping not relieved by a bowel movement

- Fatigue
- Rectal bleeding
- Iron-deficient anemia
- Weight loss (significant and unexplained)
- Fever
- Onset >40 years
- Family history of IBD or colon cancer
- Nocturnal symptoms (abdominal pain and cramping which awakes the sufferer fro sleep)[112]

The presence of alarm symptoms or an unusual finding on routine examination (e.g., thyroid abnormality) may prompt further referrals and testing. Although several symptom-driven criteria have been published, including the different Rome Foundation systems and the Manning criteria, it is important to realize that such systems have rarely been validated in IBS patients and their use to confirm or exclude the disorder is controversial.[113] This may be why previous guidelines have focused on a simple and practical definition for IBS: abdominal pain or discomfort that is accompanied by a change in bowel habits for at least 3 months (without alarm symptoms).[114] Once IBS is diagnosed, it should be further differentiated by predominant symptom pattern into IBS with diarrhea (IBS-D), IBS with constipation (IBS-C), mixed IBS or alternating bowel patterns (IBS-M), or unclassified (IBS-U).[115] Symptoms are not always stable and patients may change from one IBS subtype to the next during different stages of life. Small intestinal bacterial overgrowth or celiac sprue may be tested for in selected patients, but routine screening is not currently recommended. Because there is no known cure for IBS, it is logical to use these subgroups to help direct symptomatic therapy. In most cases, the primary-care clinician can successfully manage the IBS patient using the treatment algorithm depicted in Figure 24-3.



Diagnosis of Irritable Bowel Syndrome (IBS)
Assess need and perform patient education
Assess/treat concomitant psychiatric or other disorders
If needed have patient keep dietary/symptom diary
Determine predominant symptoms
Constipation (CP-IBS)
First-line: slowly increase dietary fiber (up to 20 g/day)
Second-line: 4–6 week trial of milk of magnesia or lactulose or polyethylene glycol or lubiprostone
Adbominal Pain (PP-IBS)
First-line: 4–6 week trial of hyoscamine as needed
Second-line: 4–6 week trial of dicyclomine as needed
Third-line: low-dose amitriptyline or nortriptyline for refractory or continuous pain
Diarrhea (DP-IBS)
First-line: loperamide as needed or prophylactic use
Second-line: 4–6 week trial of diphenoxylate w/atropine as needed
Third-line: 4–6 week trial of cholestyramine
Referral to IBS specialist if standard measures fail
Consider alosetron for selected female patients with DP-IBS
+
Consider rifaximin in IBS patients without constipation

Figure 24-3 Treatment algorithm for irritable bowel syndrome. (Source: American College of Gastroenterology Task Force on Irritable Bowel Syndrome et al. An evidence-based position statement on the management of irritable bowel syndrome. Am J Gastroenterol. 2009;104(Suppl 1):S1; Pimentel M et al. Rifaximin therapy for patients with irritable bowel syndrome without constipation. N Engl J Med. 2011;364:22.)

There are limited data concerning the natural history of IBS. IBS is generally considered a benign disease with a good prognosis.[116] Patients' symptoms often wax and wane, and, in some cases, the syndrome resolves spontaneously.

Management

PATIENT EDUCATION

CASE 24-3

QUESTION 1: V.H. is a 33-year-old woman who presents with complaints of severe abdominal pain (rated 6 on a scale of 1–10), bloating, and the passage of hard pellet-like stools about every 3 days. This has gone on for about 6 months, and V.H. notices that an "attack" occurs usually after a large meal. Her past medical history is significant for a generalized anxiety disorder. Her current medications include buspirone and Yaz (drospirenone and ethinyl estradiol). She drinks socially and does not smoke or use illicit drugs. V.H. is concerned that her symptoms are indicative of cancer. How should the clinician respond to V.H.'s concerns?

Clinicians must reassure patients with IBS that their symptoms are real but benign. An effective physician–patient relationship is important for improved patient satisfaction, adherence to therapy, and symptom reduction.[117] Furthermore, patients should be thoroughly counseled concerning the prognosis of IBS. Many patients are fearful that their symptoms are indicative of severe pathology such as cancer. Reassurance and education are vital to assuage fears and to reinforce the generally benign nature of this disorder. Involving patients at the earliest stages in their treatment plan is vital for patient acceptance and to avoid "doctor shopping." Further, some patients exhibit a phenomenon known as somatization. This is defined as a tendency to experience and communicate somatic distress in response to psychosocial stress and is a factor in how often IBS patients seek health care for their condition.[118] Educational sessions and psychological techniques are thought to decrease the risk of developing somatization, but data to date are limited concerning these interventions.[119] Unfortunately, psychological disorders are present in a large segment of IBS patients. The clinician should again reinforce the notion that IBS is not "all in the patient's head." However, treatment of comorbid disorders, including the discovery of a history of physical or sexual abuse (and possible posttraumatic stress disorder), is an important component in successfully treating IBS.[116] Thus, the initial intervention with patients of IBS should include an interactive patient education session of IBS and earning the patient's trust.

DIET AND PROBIOTICS

Food intolerance may cause symptoms similar to those associated with IBS. Patients with lactose intolerance can experience pain, bloating, and diarrhea after ingesting milk-based products. A dietary and symptom diary may reveal such an intolerance, and avoidance of the implicated foods would constitute effective treatment. Unfortunately, most patients with IBS have difficulty complying with exclusion diets or will not achieve significant relief with them.

Gluten-free diets eliminate gluten found in wheat, barley, and rye and a wide variety of processed foods, while FODMAPs diets consist of eliminating a group of short-chain carbohydrates such as fermentable oligosaccharides, disaccharides, monosaccharides, and polyols called FODMAPs because they are unable to be properly absorbed by patients with IBS and cause fermentation by bacteria in the gut producing gas.[120,121] Recent guidelines suggest that gluten-free and low FODMAPs diets show promise, but their role is still questionable.[114] Guidelines also suggest there is not enough data to recommend prebiotics or synbiotics. However, probiotics have shown promise with a decrease in flatulence or bloating, although there are no comparative studies to suggest one product over another.[114]

CASE 24-3, QUESTION 2: V.H. has gradually increased her dietary fiber, mainly bran, during the past 6 weeks. She still feels constipated and did not experience any improvement. In addition, new symptoms of abdominal bloating have occurred in the past week. What is a reasonable strategy to treat V.H.'s IBS-C?

Patients with IBS-C may benefit from increased dietary consumption of soluble fiber; with a recent study finding that psyllium significantly improved IBS symptoms during 3 months of treatment compared with placebo.[122] Insoluble fiber such as bran can worsen symptoms of bloating, cramping, or flatulence.[114] Patients should be counseled that large doses of fiber can lead to abdominal gas and bloating, and overall objective long-term evidence in IBS is lacking.

V.H. should be encouraged to keep a food diary to identify food intolerances. Currently, there is very little evidence to suggest a gluten-free or a FODMAPs diet for this patient. She can consider probiotics, but there is insufficient evidence to suggest one probiotic over the other. When choosing fiber for constipation, she should substitute bran fiber for soluble fiber, such as psyllium, to reduce abdominal gas and bloating.

CASE 24-3, QUESTION 3: Several months have passed since V.H. was first diagnosed with IBS-C. She has had therapeutic trials of several over-the-counter agents that were either poorly tolerated or lacked effectiveness. What other options are available for treating V.H.'s IBS-C?

Pharmacotherapy for Irritable Bowel Syndrome with Constipation (IBS-C)

In patients with IBS-C in whom fiber therapy fails, other standard laxatives may be tried for symptomatic relief. These may include milk of magnesia, lactulose, senna, or polyethylene glycol without electrolytes (Miralax). This last agent was shown to improve the number of bowel movements in a cohort of adolescents with IBS-C, but had no effect on abdominal pain or bloating.[123] Few well-designed trials looking at any laxative for IBS have been published. These agents are usually well tolerated, although they can occasionally cause abdominal bloating. Other adverse effects of the osmotic laxatives include diarrhea, taste disturbances, and hypermagnesemia (especially in patients with renal impairment). Although laxatives may provide relief of constipation, they will not effectively treat abdominal pain. Thus, other treatments will be required in many patients.

TEGASEROD

Stimulation of the 5-HT_4 receptor accelerates colonic transit and has been exploited as a target for pharmacotherapy of IBS-C. The first of these agents, tegaserod, was originally approved in the United States for women with IBS-C. Tegaserod is a specific 5-HT_4 partial agonist that was evaluated in women with at least a 3-month history of IBS-C symptoms.[124] Clinical studies demonstrated a modest but significant benefit with tegaserod. Unfortunately, postmarketing analysis by the US Food and Drug Administration found an increased incidence of heart attack, stroke, and unstable angina in patients receiving the drug, and in April 2008, the manufacturer of tegaserod halted all sales and marketing of this agent.

LUBIPROSTONE

Lubiprostone, a GI chloride-channel activator (CIC-2 channels) that enhances intestinal fluid secretion and acts as a laxative, was approved in the United States for IBS-C in women older than 18 years of age. The drug has several actions on GI function including increased small and large bowel transit time and decreased gastric emptying.[125] The dose of lubiprostone for IBS-C is 8 mcg orally twice daily with food and water, which is a lower dose than used for chronic idiopathic constipation. Mechanical GI obstruction is a contraindication to lubiprostone's use.[126] A recent analysis of two randomized controlled studies of lubiprostone versus placebo in women with IBS-C found that the drug was moderately effective in improving patient perception of constipation symptoms (17.9% vs. 10.1% of placebo groups responded; $p = 0.001$).[127] Primary adverse effects of lubiprostone include nausea and vomiting, but the effects are less likely at the dose of the drug approved for IBS-C and can be somewhat ameliorated by taking the medication with food.[125] Too few men with IBS-C were enrolled in the clinical trials with lubiprostone to draw any conclusions about its effectiveness in this population. Because the drug is associated with teratogenic effects in animals, the manufacturer recommends that women who could become pregnant have a negative pregnancy test before beginning therapy and be able to comply with effective contraceptive measures during therapy.[126] The drug is significantly more expensive than traditional laxatives, and should generally be reserved for patients who have failed other therapy for IBS-C.

Linaclotide

Linaclotide (Linzess) is a guanylate cyclase-C (GC-C) agonist and together with its active metabolite bind to GC-C receptors acting locally on the luminal surface of the intestinal epithelium to increase intracellular and extracellular cyclic guanosine monophosphate (cGMP) concentrations.[128] Elevated cGMP stimulates chloride and bicarbonate secretions into the intestinal lumen, resulting in increased intestinal fluid and gastrointestinal movement with decreased response to pain.

Linaclotide's approval was based on two randomized, double-blind, placebo-controlled phase III trials.[129,130] Results from clinical trials show that patients receiving linaclotide reported small but statistically significant improvements in abdominal pain, discomfort, and bloating with some improvements in bowel straining, constipation, and stool consistency compared to placebo-treated patients.[129,130] On withdrawal of linaclotide therapy, abdominal pain returned and bowel movements decreased to levels similar to the placebo group, but there was no rebound effect noted.[130] Linaclotide is approved for use in male and female adult patients >18 years at a dosage of 290 mcg daily taken 30 minutes before breakfast. There is a boxed warning for contraindicated use in children less than 6 years old and patients with known or suspected mechanical GI obstruction. Use should be avoided in children 6 to 17 years because of deaths from dehydration in younger juvenile mice.[128] Because of low systemic exposure, drug interactions are unlikely. The main side effect is diarrhea, abdominal pain, and flatulence.[128]

Because there are no head-to-head comparative trials with lubiprostone and linaclotide, both of these agents are viable options for V.H. Therefore, a trial of lubiprostone 8 mcg orally twice daily with meals or linaclotide 290 mcg daily taken 30 minutes before breakfast would be reasonable.

Irritable Bowel Syndrome–Associated Pain and Bloating

tients with IBS-C in whom fiber therapy fails, other standar

ANTISPASMODICS

CASE 24-4

QUESTION 1: L.K. is a 38-year-old woman who has a long history of abdominal pain and episodic diarrhea. L.K. works as a sales representative for a major software vendor and is called on periodically to make formal presentations. She finds that just before these presentations she experiences "attacks" of abdominal pain and diarrhea. Her past medical history is significant for fibromyalgia, which manifests as chronic tiredness and fatigue. She has no other medical problems and takes no medications. She has no known drug allergies. She does not drink, smoke, or use illicit drugs. She has undergone an extensive workup, including colonoscopy, upper GI endoscopy with small bowel follow-through, computed tomography abdominal scans, serum electrolytes, thyroid function tests, and stool studies. These procedures and tests were negative, and L.K.'s gastroenterologist has diagnosed her with IBS. L.K. currently has one to two loose stools daily. They are not greasy appearing or foul smelling. She has bouts of abdominal pain (severity of 7 on a 1–10 pain scale) with or without diarrhea several times daily. She describes the pain as "stabbing" and "cramping." She has not noted any temporal relationship to meals or that certain foods exacerbate her condition. What pharmacologic options are available for L.K.'s abdominal pain? What adverse effects are associated with these medications?

Drugs that possess smooth muscle relaxation properties, usually by anticholinergic pathways, have long been used to treat IBS. In the United States, the two most commonly prescribed antispasmodics are hyoscyamine and dicyclomine, both of which possess significant anticholinergic properties.[98] Clinical trials that have examined the use of these agents in IBS have been plagued by small numbers and methodological problems, and recently several meta-analyses have been conducted to provide insight in this area. In general, these systematic reviews have found that, as a class, smooth muscle relaxants were superior to placebo in improving abdominal pain, although they are less effective at treating other IBS symptoms.[131] Unfortunately, there seems to be significant heterogeneity when looking at the efficacy of single agents in this class. Additionally, many agents studied in clinical trials are not available in the United States. Current treatment guidelines list antispasmodics as options for pain or bloating associated with IBS. If prescribed, an as-needed strategy of use has been advocated by some experts as opposed to continuous dosing owing to anticholinergic adverse effects.[109] Peppermint oil capsules also have smooth muscle relaxation properties and have been shown to be beneficial in IBS-related pain and cramping.[132]

ANTIDEPRESSANTS

Current treatment guidelines recommend the use of either tricyclic antidepressants or selective serotonin reuptake inhibitors (SSRIs) for patients with severe or continuous abdominal pain.[114] The analgesic effects of these agents are well known, and it is believed that these agents may work by a similar mechanism in IBS-associated pain and bloating as well as global well-being. One recent meta-analysis examined the class as a whole in IBS patients and found low-dose tricyclic antidepressants significantly improved pain, bloating, and IBS symptoms compared with placebo.[133] A dose–response relationship was not noted, and low doses of tricyclic antidepressants (e.g., amitriptyline 10–25 mg at bedtime) are often effective in relieving abdominal pain and diarrhea. A 3-month trial at a target dose of a drug (e.g., amitriptyline 50 mg) should be attempted before therapeutic failure is confirmed. Secondary amine tricyclic antidepressants (nortriptyline, desipramine) are better tolerated by many patients than tertiary amines (amitriptyline, imipramine) owing to decreased anticholinergic adverse effects such as sedation, dry mouth and eyes, urinary retention, and weight gain. SSRI use is more controversial in IBS patients as conclusive evidence of efficacy is lacking.[134] Still, practice guidelines note that these agents are also reasonable agents to consider in patients with pain or bloating associated with IBS.

Information on other antidepressants for IBS symptoms is limited. A recent pilot study suggested that duloxetine may improve pain and diarrhea in IBS patients, but more data are needed before this drug can be recommended.[135] Nortriptyline 10 mg orally at bedtime should be initiated with titration to symptom relief and lack of adverse effects.

Irritable Bowel Syndrome with Diarrhea

CASE 24-4, QUESTION 2: Two weeks after L.K. starts nortriptyline 25 mg at bedtime, she reports significant relief from both her abdominal pain and fatigue. She reports that she is sleeping better, and she now rates her pain as a 2 on a 1–10 scale. Her diarrhea has improved somewhat; however, she still suffers from a "diarrhea attack" before each presentation. What other treatments are available for IBS-D? What are the risks and benefits of these treatments?

STANDARD ANTIDIARRHEALS

Small bowel and colonic transit is accelerated in patients with IBS-D; thus, drugs that slow this process should be effective in relieving diarrhea.[136] Loperamide, an opioid agonist that penetrates poorly into the central nervous system, is the preferred agent for IBS-D. Meta-analyses have found loperamide to be an effective agent for improving diarrhea and, in some cases, improving patients' global well-being.[137] As with the antispasmodics, as-needed treatment is preferred to scheduled dosing (e.g., 2–4 mg PO up to QID as needed). Prophylactic dosing before a stressful situation or an event during which bathroom access is limited is particularly effective. Diphenoxylate with atropine is generally considered a second-line agent because of its increased risk of anticholinergic adverse effects. Finally, cholestyramine is occasionally used in refractory cases of IBS-D, especially when bile acid malabsorption is suspected or confirmed.[138] This agent is often poorly tolerated as a result of palatability problems. Cholestyramine also has a significant number of drug interactions of which the clinician must be aware.

ALOSETRON

Alosetron is a highly potent 5-HT$_3$ receptor antagonist that slows colonic transit time, increases intraluminal sodium absorption, and decreases small intestinal secretions.[139] Constipation is the most frequently reported adverse effect in clinical studies (approximately 30% of alosetron patients), with approximately 10% of patients withdrawing from studies for this reason. Postmarketing reports of severe constipation with cases of bowel obstructions and ischemic colitis were reported.[140] Bowel perforation and, rarely, death were also reported with alosetron use, and the drug was voluntarily withdrawn from the market in November 2000. After extensive lobbying by several patient groups, alosetron was reintroduced to the US market in June 2002, with restricted conditions for use. Prescribers must be registered with the drug manufacturer, and patients must sign a patient–physician agreement and be provided with a written medication guide. The starting dose and regimen for alosetron is 0.5 mg BID for 1 month. If, after 4 weeks, this is well tolerated but does not adequately control IBS symptoms, then the dosage can be increased to 1 mg BID.[141] It is imperative that patients not start alosetron if they have a history of problems with constipation, bowel obstruction or ischemic colitis, IBD, or a thromboembolic disorder. Patients must immediately discontinue alosetron if they become constipated or have symptoms of ischemic colitis, such as new or worsening abdominal pain, bloody diarrhea, or blood in the stool. A recent review of the mandatory postmarketing surveillance system designed to monitor the safety of the drug found an overall low rate of ischemic colitis.[142]

Newer Agents for IBS

In May 2015, the FDA approved two new drugs, rifaximin (Xifaxan) and eluxadoline (Viberzi), to treat IBS with diarrhea. Rifaximin was previously approved for traveler's diarrhea. Because some evidence exists concerning a possible association of bacterial GI infection and IBS symptoms, this has prompted some investigators to postulate that small bowel flora overgrowth may contribute to IBS symptoms. The nonabsorbable antibiotic rifaximin had been shown in two small studies to improve global symptoms in IBS for up to 10 weeks.[143,144] More recently a report of two randomized, double-blind, placebo-controlled trials of rifaximin in IBS (without constipation) was published.[145] In this trial a 14-day course of rifaximin 550 mg TID was found to significantly improve relief of global IBS symptoms during the first 4 weeks after treatment compared with placebo. The magnitude of improvement was small, but was considered clinically relevant. Rifaximin is approved for a dosage of 550 mg TID for 14 days for IBS-D. The patient can be treated 2 times with the same regimen if there is recurrence.[146] The most common side effects in patients treated with rifaximin for IBS-D include nausea and an increase in alanine aminotransferase (ALT). Caution should be used when using rifaximin in patients with severe liver impairment.[146]

Eluxadoline is a minimally absorbed μ-opioid receptor agonist and δ-opioid receptor antagonist. Studies have shown that when there is simultaneous μ-opioid receptor agonism and δ-opioid receptor antagonism, patients will experience decreased abdominal pain and diarrhea.[147]

The dosage approved for the treatment of IBS-D is 100 mg twice daily taken with food, but the dose is reduced to 75 mg BID in patients who are unable to tolerate 100 mg BID, have no gallbladder, have mild to moderate liver impairment, or are on organic anion transporting polypeptides (OATP1B1) inhibitors.[148] Patients treated with eluxadoline had better clinical response in phase 2 trials with decreased abdominal pain and increase stool consistency without significant risk of constipation.[147] The most common side effects in patients treated with eluxadoline include constipation, nausea, and abdominal pain.[148] The most serious known risk associated with eluxadoline is the risk of sphincter of Oddi spasm, which can result in pancreatitis. Eluxadoline should not be used in patients with a history of bile duct obstruction, pancreatitis, severe liver impairment, or severe constipation, and in patients who drink more than three alcoholic beverages daily.[148] Patients should be counseled to avoid alosetron or loperamide in combination with eluxadoline on a chronic basis, although it can be used on an acute as needed basis. If signs of constipation occur, the patient must be advised to discontinue loperamide immediately. They must discontinue eluxadoline if they experience constipation for more than 4 days. Patients should also be advised to avoid concomitant use of anticholinergics and other opioids with eluxadoline to avoid constipation. They should be reminded that eluxadoline has a potential for drug abuse.[148]

In L.K.'s case, initiation of loperamide 2 mg as needed before a stressful situation would be a cost-effective approach to her symptoms. Should her symptoms worsen or her current regimen lose effectiveness, eluxadoline 100 mg BID with food is an alternative, while a course of rifaximin 550 mg TID for 14 days would be considered an alternative strategy if she fails eluxadoline. The patient should be advised not to combine these therapies for chronic treatment and discontinue eluxadoline if she experiences constipation for 4 days.

Complications of End-Stage Liver Disease

Yasar O. Tasnif and Mary F. Hebert

CORE PRINCIPLES	CHAPTER CASES
ASCITES	
1 Cirrhosis is defined as the fibrosis of the hepatic parenchyma, resulting in altered hepatic function, restricted venous outflow, and portal hypertension. Cirrhosis results in an overall vasodilated state, activation of the renin–angiotensin–aldosterone system, altered hepatic synthetic function, and development of complications such as ascites and other complications of cirrhosis.	**Case 25-1 (Question 2)**
2 Physical findings of ascites can include the presence of an enlarged fluid-filled abdomen, increased abdominal girth, a positive fluid wave, increased body weight and is often accompanied by peripheral edema. The goals of treatment for ascites are to mobilize ascitic fluid, diminish abdominal discomfort, as well as to prevent complications such as bacterial peritonitis and respiratory distress.	**Case 25-1 (Questions 1, 3)**
3 The treatment for ascites involves sodium restriction (2 g/day), water restriction for severe dilutional hyponatremia, and the use of spironolactone and furosemide (100:40 mg ratio). Management and monitoring of ascites includes ensuring adequate weight loss, maintaining electrolyte balance, and preventing complications of diuretic therapy.	**Case 25-1 (Questions 4–8)**
4 In cases of refractory ascites (diuretic-resistant), large-volume paracentesis, along with albumin replacement, is often indicated. Transjugular intrahepatic portosystemic shunt (TIPS), surgical shunts, and liver transplantation are the options for the treatment of refractory ascites when paracentesis is deemed ineffective, or in patients who are intolerant or who have a contraindication to paracentesis.	**Case 25-1 (Questions 9–11)**
5 Spontaneous bacterial peritonitis (SBP) is a common complication of ascites. Prophylactic regimens include the long-term administration of oral antibiotics such as fluoroquinolones (norfloxacin) or trimethoprim-sulfamethoxazole to prevent the recurrence of SBP. Recommendations also include the administration of antibiotic prophylaxis for prevention of SBP in patients with variceal hemorrhage.	**Case 25-2 (Question 4)**
ESOPHAGEAL VARICES	

1 Because esophageal varices are directly related to the severity of portal hypertension, the treatment is aimed at primary prevention of bleeding by reduction of portal pressure with the use of nonselective β-blockers, and/or elimination of the varices with endoscopic variceal ligation (EVL). Treatment approaches depend on the risk of hemorrhage.	**Case 25-2 (Question 5)**
2 Secondary prophylaxis to prevent recurrent bleeding episodes includes the combination of nonselective β-blockers and EVL. TIPS may be an option in patients who experience recurrent variceal hemorrhage despite combination of pharmacologic and endoscopic therapy.	**Case 25-2 (Question 6)**

3 Acute variceal bleeding is considered a medical emergency and should be treated immediately. Treatment goals include volume resuscitation, acute treatment of bleeding, and prevention of recurrence of variceal bleeding. For the control and management of acute hemorrhage, the combination of pharmacologic therapy and variceal ligation is the preferred approach. In cases of acute variceal bleeding uncontrolled by pharmacologic and endoscopic therapy, TIPS can be an effective option.	**Case 25-2 (Questions 1–3)**

HEPATIC ENCEPHALOPATHY

1 Hepatic encephalopathy is a metabolic disorder of the central nervous system that occurs in patients with either advanced cirrhosis or fulminate hepatic failure. The clinical features include altered mental state and asterixis. Several theories exist about the pathogenesis of hepatic encephalopathy; however, it is likely multifactorial. Precipitating causes can include GI bleeding, diuretic-induced hypovolemia and/or electrolyte abnormalities, metabolic alkalosis, as well as sedating drugs.	**Case 25-3 (Questions 1–3)**
2 After identifying and removing precipitating causes of hepatic encephalopathy, therapeutic management is aimed primarily at reducing the amount of ammonia or nitrogenous products in the circulatory system by limiting protein intake and by the use of lactulose. Other therapeutic options include rifaximin and neomycin.	**Case 25-3 (Questions 4, 5)**
3 Monotherapy with lactulose should be tried first. If satisfactory results do not occur, switching to another option (rifamixin or neomycin) or combination therapy should be considered.	**Case 25-3 (Question 6)**

HEPATORENAL SYNDROME

1 Hepatorenal syndrome (HRS) is a complication of advanced cirrhosis and is diagnosed by exclusion of other known causes of kidney disease. The definitive treatment for type 1 and type 2 HRS is liver transplantation, which is the only treatment that assures long-term survival. The main goal of pharmacologic therapy is to reverse HRS sufficiently so that appropriate candidates for liver transplantation can survive until suitable donor organs can be procured.	**Case 25-3 (Questions 7, 8)**

OVERVIEW

According to the National Vital Statistics Report published by the Centers for Disease Control and Prevention, chronic liver disease and cirrhosis is the 12th leading cause of death in the United States, accounting for approximately **38,170** deaths each year.[1] Cirrhosis, or end-stage liver disease, can be defined as fibrosis of the hepatic parenchyma resulting in nodule formation and altered hepatic function, which results from a variety of causes. Although there are other common causes of cirrhosis, most cases of cirrhosis worldwide result from chronic viral hepatitis or chronic alcohol consumption.[2] This chapter describes the pathogenesis of cirrhosis and the associated complications of portal hypertension (esophageal varices, gastric varices, ascites, spontaneous bacterial peritonitis, hepatic encephalopathy, and hepatorenal syndrome) and their treatment.

PATHOGENESIS OF CIRRHOSIS

The liver consists of the hepatic parenchyma (hepatocytes) and a large proportion of nonparenchymal cells, including sinusoidal endothelial cells, Ito cells, and macrophages. Most of the liver's role in detoxification takes place within the hepatocytes. Also within the liver is the biliary tree in which bile drains from the liver and some substances are actively transported into the bile.[3] The liver has a strong capacity to regenerate; however, ethanol and hepatitis viruses can impair this.[4]

Liver injury leading to cirrhosis impairs hepatic function. Steatosis from ethanol is characterized by lipid deposition in the hepatocytes, which is followed by liver inflammation (steatohepatitis), hepatocyte death, and collagen deposition leading to fibrosis.[5] Oxidative stress appears to play a role in ethanol-induced liver injury. It is important to note that not all heavy drinkers experience liver cirrhosis.[6] Factors such as sex, genetic predisposition, and chronic viral infection also play a role in the development and progression of ethanol-induced liver disease.[7]

Hepatitis C virus (HCV) affects millions of people worldwide. Approximately a third of those chronically infected are predicted to progress to cirrhosis or hepatocellular carcinoma.[8] The progression of liver disease in patients with HCV is dependent on both patient and viral factors. Multiple mechanisms are proposed to play a role in liver injury associated with HCV infection, such as diminished immune clearance of HCV, oxidative stress, hepatic steatosis, increased iron stores, and increased rate of hepatocyte apoptosis.[9] Because not all patients infected with HCV experience cirrhosis, factors other than viral clearance, such as individual immune response, age, sex, hepatic iron content, and HCV genotype, are all implicated as cofactors in the development of cirrhosis.[10]

Among other causes, autoimmune hepatitis, primary biliary cirrhosis, primary sclerosing cholangitis, biliary atresia, metabolic disorders (e.g., Wilson disease and hemochromatosis), chronic inflammatory conditions (e.g., sarcoidosis), and vascular derangements can lead to hepatic fibrosis and cirrhosis.[2] Approximately 20% of Americans have nonalcoholic fatty liver disease (NAFLD), which in most cases have no symptoms. Risk factors commonly associated with the development of NAFLD include obesity, hyperlipidemia, and diabetes. Although corticosteroids can cause fatty liver, NAFLD diagnosis excludes corticosteroids and other causes of fatty liver. Nonalcoholic steatohepatitis (NASH) is a more serious form of NAFLD, which can lead to cirrhosis. Evidence suggests that insulin resistance and lipid peroxidation play a role in the pathogenesis of this condition.[11,12] Regardless of the cause of end-stage liver disease, the most frequent complications of portal hypertension are esophageal or gastric varices, ascites, hepatic encephalopathy, and hepatorenal syndrome.[13]

COMPLICATIONS OF CIRRHOSIS

Portal Hypertension

The portal vein begins as a confluence of the splenic, superior mesenteric, inferior mesenteric, and gastric veins and ends in the sinusoids of the liver (Fig. 25-1). Blood in the portal vein contains substances absorbed from the intestine and delivers these substances to the liver to be metabolized before entering the systemic circulation. Once the portal blood reaches the liver, it crosses through a high-resistance capillary system within the hepatic sinusoids.

In cirrhosis, increased intrahepatic resistance results from intrahepatic vasoconstriction that is hypothesized to be caused by a deficiency in intrahepatic nitric oxide (NO).[14] Increased intrahepatic resistance also results from an enhanced activity of vasoconstrictors and structural changes from liver regeneration, sinusoidal compression, and fibrosis.

Portal hypertension results from both an increase in resistance to portal flow and an increase in portal venous inflow because of splanchnic vasodilatation from increased NO production in the extrahepatic circulation.[15]

Figure 25-1 Schematic diagram of the portal venous system.

Direct portal pressure measurement is invasive and not routinely performed. The hepatic venous pressure gradient (HVPG), which reflects the gradient between the portal vein and vena cava pressure, is another accurate, safe, and less-invasive procedure, widely accepted as the portal venous pressure gradient.[16–18] Normal portal pressure is generally below 6 mm Hg, and in cirrhotic patients, it may increase to 7 to 9 mm Hg. Clinically significant portal hypertension develops when portal pressure exceeds 10 to 12 mm Hg, resulting in complications such as esophageal varices and ascites.[17,19] Portal hypertension can be further classified as prehepatic (e.g., splenic, portal vein thrombosis), intrahepatic (e.g., hepatic cirrhosis and fibrosis), or posthepatic portal hypertension (e.g., inferior vena cava obstruction, right-sided heart failure).[20–22] Persistent portal hypertension may (a) change both blood flow and the lymphatic circulation and lead to ascites formation; (b) increase pressure in the vessels that branch off the portal vein, such as the coronary veins, leading to the formation of esophageal varices; and (c) lead to the development of increased abdominal collateral circulation. Hepatic encephalopathy and hepatorenal syndrome are other complications associated with advanced cirrhosis and portal hypertension.[20–22] The American Association for the Study of Liver Diseases and European Association for the Study of the Liver Single-Topic Conference classified cirrhosis into two main categories, compensated and decompensated. Patients can be cirrhotic with a portal pressure less than 10 mm Hg and an absence of the complications of cirrhosis (e.g., ascites, variceal hemorrhage, or encephalopathy) and thus would be considered to be compensated. This is in contrast to a patient presenting with ascites, esophageal hemorrhage, hepatic encephalopathy, and/or hepatorenal syndrome, which are present in decompensated cirrhosis.[23] Patients with compensated cirrhosis are managed by treatment of the underlying cause as well as prevention (primary prophylaxis) and early diagnosis of the complications. For patients with decompensated cirrhosis, the aim is to treat the complications and prevent sequela (secondary prevention).[24]

LABORATORY FINDINGS

Laboratory evaluations in cirrhosis may not reflect the extent of the parenchymal necrosis, regeneration, and fibrotic nodular scarring. Conventional liver “function” tests, such as the serum aminotransferases (aspartate aminotransferase [AST, formerly known as SGOT], alanine aminotransferase [ALT, formerly known as SGPT]), and alkaline phosphatase, are actually better characterized as liver “injury” tests and are modestly helpful to the clinician screening for hepatobiliary disease and monitoring injury progression. These tests, however, do not quantitatively measure the functional capacity of the liver. The aminotransferases are released during the normal turnover of liver cells (see Chapter 2, Interpretation of Clinical Laboratory Tests). High serum concentrations of aminotransferases suggest enzyme release from injured hepatocytes. Serum concentrations of AST and ALT may initially rise very high with acute liver injury and then fall when the etiology is removed or necrosis is so severe that few hepatocytes remain.

Because alkaline phosphatase is present in high concentrations in biliary canaliculi (as well as bone, intestines, kidneys, placenta, and white blood cells [WBCs]), its concentration increases more with biliary than hepatocellular injury. High serum concentrations of gamma glutamyl transpeptidase and bilirubin are also suggestive of biliary injury. Elevated serum concentrations of alkaline phosphatase, AST, and/or ALT may suggest hepatic injury, but because they are also found in other tissues, their elevation is not diagnostic for liver disease.[25,26]

Serum concentrations of proteins (e.g., albumin), clotting factors, prothrombin time (PT), and international normalized ratio (INR) provide insight into liver function. Albumin is synthesized entirely by the liver; therefore, concentrations reflect hepatocellular function to some degree. However, changes in albumin concentration are nonspecific, because they are influenced by other factors, including poor nutrition, renal wasting (proteinuria), and gastrointestinal (GI) losses. Prothrombin time is also nonspecific, since it is prolonged in vitamin K deficiency from poor nutrition or fat malabsorption as well as biliary obstruction (cholestasis).[27]

Table 25-1

Child-Turcotte-Pugh Classification of Severity of Liver Disease

	Score[a]		
	1 Point	**2 Points**	**3 Points**
Bilirubin (mg/dL)	<2	2–3	>3
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
INR	<1.7	1.7–2.3	>2.3
Ascites	None	Mild to moderate	Severe
Encephalopathy (grade)	None	Mild to moderate (1 and 2)	Severe (3 and 4)

[a] Class A, 5–6 points; class B, 7–9 points; class C, 10–15 points. INR, international normalized ratio.

Allocation priority in non-urgent liver transplantation: an overview of proposed scoring systems. Dig Liver Dis. 2009;41:700.

A number of the factors described above are included in the Child–Turcotte–Pugh classification of liver disease severity (Table 25-1).[28,29] This scoring system helps clinicians grade disease severity, and predicts the long-term risk of mortality and quality of life. A person with Child–Turcotte–Pugh class A cirrhosis may survive 15 to 20 years, whereas those with class C may survive only 1 to 3 years.[30] The main limitation of the Child–Turcotte–Pugh classification is the subjective nature of some factors, such as ascites and hepatic encephalopathy, which are subject to clinical interpretation and may be altered by therapy.[31,32] As a general guide, and not a rule, class A patients are considered to be compensated, and classes B and C decompensated.[24]

An alternate method for assessing survival in patients with liver disease is the Model for End-Stage Liver Disease (MELD) score, which is calculated by the formula[32]:

$$\text{MELD Score} = (0.957 \times \text{In}[\text{Creatinine mg/dL}] + 0.378 \times \text{In}[\text{total bilirunbin mg/dL}] + 1.120 \times \text{In}\,[\text{INR}] + 0.643 \times 10 \qquad \textbf{(Eq. 25-1)}$$

Because of the good correlation between the MELD score and short-term (3-month) mortality as well as the objective nature of the system, it replaced the Child–Turcotte–Pugh score in the United Network for Organ Sharing (UNOS) prioritization of organ allocation of cadaveric livers for transplantation.[33–35] MELD scores range from 6 (less ill) to 40 (gravely ill) with highest scores given priority for organ allocation with the exception of Status 1A adult patients (acute and severe onset of liver failure, who have a life expectancy of hours to a few days without liver transplantation) who are given highest priority.[36]

CLINICAL PRESENTATION

CASE 25-1

QUESTION 1: R.W. is a 54-year-old man with a 2-week history of nausea, vomiting, and lower abdominal cramps without diarrhea. Despite chronic anorexia, he has managed to drink a fifth of vodka (750 mL) and eat about two meals a day for the past 2 years. During this time, he experienced a 30-lb weight loss. He began drinking 9 years ago when his wife became disabled after diagnosis of a brain tumor. Two years ago, his alcohol consumption increased from one pint to a fifth daily. Recently, he has noted bilateral edema of his legs, an increased tenseness and girth of his abdomen, jaundice, and scleral icterus. His medical history is noncontributory, other than a history of spontaneous bacterial peritonitis (SBP) 6 months ago. He is not taking any medications and has no known drug allergies.

Physical examination reveals an afebrile, jaundiced, and cachectic male in moderate distress. Spider angiomas were found on his face and upper chest. In addition, palmar erythema was noted.

Abdominal examination reveals prominent veins on a very tense abdomen. The liver edge is percussed below the right costal margin and ascites is noted by shifting dullness and a fluid wave. The spleen is not palpable. On neurologic examination, R.W. is awake and oriented to person, place, and time. Cranial nerves II to XII are grossly intact, but a decrease in vibratory sensation of the lower extremities is noted bilaterally. Admission laboratory data are as follows:

Sodium, 135 mEq/L
Chloride, 95 mEq/L
Potassium, 3.8 mEq/L
Bicarbonate, 25 mEq/L
Blood urea nitrogen (BUN), 15 mg/dL
Serum creatinine (SCr), 1.4 mg/dL
Glucose, 136 mg/dL
Hemoglobin (Hgb), 11.2 g/dL

Hematocrit (Hct), 33.4%
AST, 212 IU
ALT, 110 IU
Alkaline phosphatase, 954 IU
PT, 13.5 (INR, 1.1)
Total/direct bilirubin, 18.8/10.7 mg/dL
Albumin, 2.3 g/dL
Guaiac positive stools

On admission to the hospital, the impression is alcoholic cirrhosis, ascites, and heme-positive stools. What subjective and objective evidence are compatible with alcoholic cirrhosis in R.W.?

R.W.’s liver function tests (elevated ALT, AST, alkaline phosphatase, and bilirubin) and physical findings (enlarged, palpable liver edge; jaundice; spider angiomas; palmar erythema; and cachexia) are consistent with advanced alcoholic cirrhosis in a patient with a history of chronic alcohol abuse. The prolonged PT and hypoalbuminemia suggest impaired hepatic synthesis of both albumin and vitamin K–dependent clotting factors. The low albumin contributes to both ascites and edema. The bilirubin of 18.8 mg/dL suggests that vitamin K absorption may be a factor in the prolonged PT. The presence of ascites (an enlarged fluid-filled abdomen) and prominent abdominal veins are suggestive of portal hypertension. A biopsy of the liver may establish the presence and severity of cirrhosis. R.W.’s prolonged PT, however, will increase the risk of bleeding from a liver biopsy. His positive guaiac finding could be indicative of bleeding esophageal varices or from another GI source. This needs to be confirmed by endoscopy. He is oriented to person, place, and time, but full hepatic encephalopathy evaluation is needed. R.W.’s calculated MELD score is 22, which predicts a 90-day mortality of approximately 20%.[33] A patient’s MELD score may increase or decrease for a period of time depending on the patient’s clinical status and treatment. A number of MELD scores will be calculated if R.W. is listed as a transplantation candidate to determine his status for organ allocation.[36] Muscle wasting and poor nutrition are the most common causes of weight loss in patients with alcoholic cirrhosis (see Chapter 90, Substance Abuse Disorders).

ASCITES

Pathogenesis of Ascites

CASE 25-1, QUESTION 2: What physiologic mechanism predisposes R.W. to fluid accumulation in the peritoneal cavity?

Ascites, or accumulation of fluid in the peritoneal cavity, is the most commonly encountered clinical symptom of cirrhosis.[24,37] This complication can be detected during physical examination when more than 3 L of fluid have accumulated. In addition to an obviously enlarged abdomen, R.W. was found to have a positive fluid wave and shifting dullness, indicating that the abdominal enlargement is not simply obesity. If the diagnosis is in doubt, which sometimes occurs in obese patients, ascites can be confirmed with ultrasound. Generally speaking, in obesity the abdomen enlarges over time (months to years), in contrast to ascites where abdominal enlargement can occur over a few weeks.[38] Once ascites develops, the 1-year patient survival rate falls to ~50%.[24]

In cirrhosis, high hepatic venous pressure leads to high intrasinusoidal pressure and development of ascites across the hepatic capsule.[39] The systemic compensation to the generalized vasodilation in cirrhosis is increased cardiac output as well as sodium and water retention through activation of the renin–angiotensin–aldosterone system (RAAS).[40] R.W.'s hypoalbuminemia (2.3 g/dL), RAAS activation, exudation of fluid from the splanchnic capillary bed and the liver surface when the drainage capacity of the lymphatic system is exceeded, and decreased ability of fluid to be contained within the vascular space owing to impaired hepatic albumin synthesis contributes to the development of ascites.

Goals of Therapy

CASE 25-1, QUESTION 3: What are the therapeutic goals in the treatment of R.W.'s ascites?

The goals of treatment for R.W.'s ascites are to treat the cause of cirrhosis by ceasing alcohol consumption; mobilize ascitic fluid; diminish abdominal discomfort, back pain, and difficulty in ambulation; as well as to prevent complications (e.g., bacterial peritonitis, hernias, pleural effusions, hepatorenal syndrome, and respiratory distress).[38] After the initial resolution of significant edema, the goal is a weight loss of 0.5 kg/day, which corresponds to a net fluid volume loss of about 0.5 L/day. Treatment of ascites in R.W. should be undertaken cautiously and gradually because acid–base imbalances, hypokalemia, or intravascular volume depletion caused by overly aggressive therapy can lead to compromised renal function, hepatic encephalopathy, and death.[41,42] The initial medical management of ascites involves restriction of sodium intake and the use of diuretics to promote salt and water excretion.[38]

Fluid and Electrolyte Balance

URINARY NA:K RATIO

CASE 25-1, QUESTION 4: The 24-hour urinary electrolytes for R.W. were as follows:

Na, 10 mEq/L
K, 28 mEq/L

Why would sodium or water restriction be appropriate (or inappropriate) for R.W.?

Normally, urine electrolytes mirror serum electrolytes (i.e., sodium concentration is greater than that of potassium). A reversal of this pattern (i.e., potassium exceeding sodium) may indicate a relative hyperaldosteronism secondary to diminished renal blood flow and low oncotic pressure. A small study by Trevisani et al.[43] evaluated renal sodium and potassium handling and plasma aldosterone in a 24-hour period in cirrhotic patients without ascites, with ascites, and healthy controls. Plasma aldosterone was significantly higher in patients with ascites, resulting in reduced renal sodium excretion, and more than doubling renal potassium excretion in comparison to healthy controls.[43] For urine electrolyte monitoring to be meaningful, the first sample must be obtained before initiating diuretics.[44,45]

SODIUM RESTRICTION

Although serum sodium in patients with ascites is often low, they are total body sodium overloaded. Sodium restriction has been shown to enhance mobilization of ascites, because fluid loss and weight change are directly related to sodium balance in patients with portal-hypertension–related ascites.[46] This finding has been incorporated into the American Association for the Study of Liver Diseases (AASLD) guidelines for the treatment of ascites. The AASLD recommends that dietary sodium should be restricted to 2,000 mg/day (88 mmol/day) and R.W. should be advised to limit his sodium intake accordingly.[38] Historically, bed rest has been advocated; however, no controlled trials support this practice.[38,42]

WATER RESTRICTION

A large prospective, observational study[47] reported that hyponatremia (sodium <135 mEq/L) is common in patients with cirrhosis, associated with poor ascites control and a greater frequency of hepatic encephalopathy, hepatorenal syndrome, and spontaneous bacterial peritonitis compared to patients with normal serum sodium concentrations.[47] In addition, very low serum sodium concentrations (<120 mEq/L) are independent from the MELD score in predicting 3- to 6-month mortality. The AASLD recommends that water restriction should be implemented in cirrhotic patients who have severe dilutional hyponatremia (serum Na <125 mEq/L).[38] Water restriction is not indicated for R.W. at this time because his serum sodium concentration is within normal limits (135 mEq/L).

VASOPRESSIN RECEPTOR ANTAGONISTS

A complete discussion of vasopressin receptor antagonists can be found in Chapter

27, Fluid and Electrolyte Disorders. The AASLD guidelines do not recommend the use of vasopressin (V2) receptor antagonists because of the lack of evidence of efficacy in patients

---

with cirrhosis, side effects, as well as the low cost-effectiveness of these medications.[38] However, it is possible that with more evidence from clinical trials, this class of medications may find a niche in the treatment of hyponatremia in cirrhotic patients.

Diuretic Therapy

CHOICE OF AGENT

CASE 25-1, QUESTION 5: R.W. was prescribed sodium restriction after initial evaluation. Spironolactone 100 mg/day and furosemide 40 mg/day were ordered to induce diuresis. Why is spironolactone preferred over other diuretics in the treatment of ascites?

Most patients with cirrhosis have elevated plasma concentrations of aldosterone.[48] High serum concentrations of aldosterone may be attributed to both increased production and decreased excretion of the hormone. Increased portal pressure, ascites, depletion of intravascular volume, and decreased renal perfusion can lead to activation of the RAAS.[49] In addition, hepatic shunting also increases aldosterone production by decreasing renal blood flow.[50] The liver metabolizes aldosterone, and hepatic impairment prolongs the physiologic half-life of aldosterone.[51] The AASLD consensus guidelines recommend the use of spironolactone as the initial diuretic of choice in the treatment of ascites.[38] Although no large comparative studies have evaluated different diuretics as first-line treatment of ascites, spironolactone is a rational diuretic choice for R.W. based on its aldosterone antagonist activity. Perez-Ayuso et al.[52] conducted a small randomized trial to study the efficacy of furosemide versus spironolactone in non-azotemic cirrhotic patients with ascites. They reported a higher response to spironolactone than furosemide (18/19 vs. 11/21; $p < 0.01$). Of the 10 nonresponders to furosemide, 9 responded to spironolactone. The authors also found that patients with higher renin and aldosterone levels did not respond to furosemide and required higher doses of spironolactone to achieve a diuretic response.[52]

Some clinicians may initiate spironolactone at a dose of 25 mg once or twice daily; however, much larger doses (100–400 mg/day) are generally necessary to antagonize the high circulating levels of aldosterone in patients with ascites.[38] The diuretic effect is enhanced when spironolactone is combined with sodium restriction.[42] In addition, furosemide can be started to minimize the risk of hyperkalemia and enhance diuresis. The AASLD guidelines recommend starting spironolactone 100 mg and furosemide 40 mg/day simultaneously and maintaining a 100:40 mg ratio. The doses of both oral diuretics can be increased simultaneously every 3 to 5 days (maintaining the ratio) to achieve adequate response. Usual maximal doses are 400 mg/day of spironolactone and 160 mg/day of furosemide.[38] In patients without renal failure, sodium restriction and diuretic therapy are effective in 90% of patients with ascites.[38,53]

Triamterene and amiloride can be used as alternatives to spironolactone if intolerable side effects (e.g., gynecomastia) occur with spironolactone.[54,55] In a small trial,[56] non-azotemic, cirrhotic patients with ascites were randomly assigned to receive amiloride (20–60 mg/day) or potassium canrenoate (150–500 mg/day, an active metabolite of spironolactone not available in the United States). A higher response rate was seen in the canrenoate group versus the amiloride group (14/20 vs. 7/20; $p < 0.025$). The authors also assessed plasma aldosterone activity and found that all responders to amiloride had normal plasma aldosterone concentrations, and all nonresponders to amiloride who later responded to potassium canrenoate had increased levels of plasma aldosterone.[56]

Eplerenone (a selective aldosterone blocker, more specific for the aldosterone receptor with a lower affinity for progesterone and androgen receptors than spironolactone) has been studied in patients with heart failure, hypertension, and renal disease.[57,58] The usual dose for eplerenone is 25 to 50 mg/day,[59] with no dosage adjustment needed in mild-to-moderate liver disease. However, severe liver disease has not been studied.[60] Approximately 10% of patients treated with spironolactone develop gynecomastia or breast pain, with 2% requiring drug discontinuation.[61] In contrast, gynecomastia occurs at a similar rate with eplerenone as with placebo (0.5%).[62,63] Unfortunately, eplerenone is much more expensive than spironolactone.[63] The lower risk of gynecomastia with eplerenone may make it a useful alternative to spironolactone; however, given its higher cost and the lack of data in the treatment of ascites in patients with severe liver disease, its role in ascites treatment remains unclear.

R.W. should receive spironolactone 100 mg and furosemide 40 mg simultaneously (maintaining a 100:40 mg ratio) as recommended by the AASLD.[38] R.W. should be carefully monitored for diuretic complications and clinical response (see Case 25-1, Questions 6–8).

MONITORING

Clinical Responses

CASE 25-1, QUESTION 6: What clinical responses should be monitored to ensure the therapeutic effectiveness of spironolactone therapy for R.W.?

Because ascitic fluid is slow to re-equilibrate with vascular fluid, diuresis greater than 0.5 to 1 kg/day (>0.5–1 L) may be associated with volume depletion, hypotension, and compromised renal function.[38] Patients may tolerate a faster diuresis if peripheral edema is present. Once edema has resolved, a scaled-back weight loss, not to exceed 0.5 kg/day, can be used as a rule of thumb to minimize the risk of renal insufficiency induced by plasma volume contraction and other diuretic-induced complications.[38,64] Monitoring body weight and abdominal girth are routinely performed in both the inpatient and outpatient settings. Monitoring fluid intake and urine output are performed primarily for inpatients, owing to practical constraints in the outpatient setting. Ideally, urine output should exceed fluid intake by about 300 to 1,000 mL/day. These measurements do not account for nonrenal fluid losses; therefore, total fluid loss will be somewhat higher. Abdominal girth measurement (circumference around the abdomen) is subject to error, because of its dependence on patient position and measurement location on the abdomen.[65] Attempts should be made to standardize patient position (e.g., sitting at a 45-degree angle) and location of measurement (level of umbilicus) to minimize variability in abdominal girth measurements.

Laboratory Parameters

CASE 25-1, QUESTION 7: What laboratory parameters could be monitored to assess the therapeutic efficacy of R.W.'s spironolactone treatment?

Serum concentrations of creatinine and urine chemistries (sodium and potassium) can be monitored to define and guide the need for increasing dosage of spironolactone. A low baseline urine Na:K ratio (<1.0) suggests high intrinsic aldosterone activity and that larger dosages of spironolactone may be needed, as is the case for R.W. If necessary, the dosage of diuretic therapy may be doubled after a few days.[49] AASLD recommends increasing both spironolactone and furosemide simultaneously every 3 to 5 days (maintaining a 100:40 mg ratio) to achieve adequate diuresis and maintain a normal serum potassium.[38]

DIURETIC COMPLICATIONS AND MANAGEMENT

CASE 25-1, QUESTION 8: The spironolactone and furosemide dosages were increased to 200 and 80 mg/day (maintaining a 100:40 mg ratio). What potential complications from the diuretic therapy might arise in R.W. and how can they be minimized?

Electrolyte and Acid–Base Disturbances

Hyponatremia, hyperkalemia, metabolic alkalosis, and, uncommonly, hypokalemia occur as side effects of diuretic therapy in patients with ascites. Hyponatremia results from a reduction in free water clearance (dilutional hyponatremia). Diuresis exacerbates hyponatremia by causing volume depletion and antidiuretic hormone (ADH) release. Hyponatremia usually can be corrected by temporary withdrawal of diuretics and free water restriction.[53,66–68] Although serum sodium may be low, these patients are total body sodium overloaded. Hyperkalemia is common in patients with refractory ascites and impaired renal function requiring high doses of diuretics such as spironolactone. Hyperkalemia can be approached in multiple ways, depending on the clinical situation (see Chapter 27, Fluid and Electrolyte Disorders). Furosemide is added to spironolactone to maintain normal serum potassium.[38] Decreasing or holding spironolactone may be appropriate depending on the patient's renal function and serum potassium.[24] Metabolic alkalosis, a result of loop diuretics, occurs because of increased urinary hydrogen loss from enhanced distal hydrogen secretion. Hypokalemia often accompanies metabolic alkalosis owing to loop diuretics.[67] Furosemide can be temporarily withheld in patients presenting with hypokalemia.[38] R.W. has some degree of renal impairment (SCr, 1.4 mg/dL) and is receiving spironolactone and furosemide. Therefore, his electrolytes and renal function tests should be monitored daily while hospitalized. After hospital discharge, monitoring will be dictated by the stability of the patient and need for diuretic dosage adjustments. For example, outpatients may need electrolytes and renal function monitoring once or twice weekly early after hospital discharge to as infrequently as every 3 months for very stable patients.[38]

Pre-renal Azotemia

Pre-renal azotemia usually results from over diuresis with subsequent compromise of intravascular volume and decreased renal perfusion. In addition to looking for clinical signs of hypovolemia, such as dizziness, orthostatic hypotension, and increased heart rate, frequent measurements of BUN and serum creatinine concentrations provide a relatively simple means of assessing the intravascular volume. A gradual rise in serum creatinine, BUN, as well as the BUN:serum creatinine ratio can serve as a warning to slow the rate of diuresis.[69] In a small study,[64] serial measurements of plasma volume and ascites volume were made during treatment with diuretics in patients with cirrhosis. Patients with ascites and no edema were able to mobilize more than 1 L/day during rapid diuresis, but at the expense of plasma volume contraction and renal insufficiency. Patients with peripheral edema appear to be somewhat protected from these effects and may safely undergo diuresis at a more rapid rate (>2 kg/day) until edema resolves.[64] Others suggest, however, that the maximal daily fluid loss should not exceed more than 0.5 L/day (>0.5 kg/day) for patients with ascites alone or 1 L/day (>1 kg/day) for those with both ascites and edema to prevent plasma volume depletion and decreased renal perfusion. If faster removal of ascites is required because of respiratory distress, large-volume paracentesis may be more effective than rapid diuresis (see Case 25-1, Question 9).[38,45,70,71] In cirrhotic patients, azotemia may also occur because of nonsteroidal anti-inflammatory drugs (NSAIDs). All NSAIDs should be discontinued, except low dose aspirin in patients at high risk for a cardiac or neurological event.[38]

Because R.W. presented with both edema and ascites, an initial weight loss of up to 1 kg/day would be reasonable with slowing to 0.5 kg/day when the edema resolves. Gradual diuresis avoids diuretic-induced depletion of intravascular fluid volume by permitting ascitic fluid to equilibrate with intravascular fluid. Long-term management of ascites is done in the outpatient setting. Severe cases with respiratory distress or impaired ambulation as well as patients with spontaneous bacterial peritonitis (see Chapter 70, Intra-Abdominal Infections) require hospitalization. If outpatient therapy is an option, a weekly evaluation initially would be prudent to prevent over diuresis and electrolyte disturbances.[38]

Refractory Ascites

CASE 25-1, QUESTION 9: Over the next several days, R.W.'s spironolactone dosage was increased to 400 mg/day. Furosemide was simultaneously increased to 80 mg BID without major improvement in diuresis. Laboratory data revealed that R.W.'s SCr had increased to 3.2 mg/dL (estimated creatinine clearance: 26 mL/minute) and his BUN had increased to 45 mg/dL. Serum electrolytes were as follows:

K, 3.1 mEq/L
Na, 130 mEq/L
Cl, 88 mEq/L
Bicarbonate, 32 mEq/L

R.W. became progressively short of breath because of restricted diaphragmatic movement secondary to his significantly enlarged abdomen. What therapeutic measures are appropriate for R.W.'s refractory (diuretic-resistant) ascites?

The AASLD guidelines mention a few treatment options for refractory ascites. Midodrine 7.5 mg given 3 times daily to increase blood pressure in hypotensive patients could possibly convert diuretic-resistant patients to diuretic-sensitive. In addition, discontinuation of β-blockers is recommended since these drugs are associated with increased mortality in patients with refractory ascites. The guidelines also mention avoiding angiotensin converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) because of the risk of hypotension.[38]

Because of the increase in SCr and respiratory distress, R.W.'s ascites treatment needs modification. Patients with cirrhosis experiencing respiratory distress despite diuretic therapy, sodium restriction, and appropriate management of hypotension (discontinuation of β-blockers and adding midodrine) may warrant more aggressive second-line treatment, including large-volume paracentesis, shunting procedures, or both.[38] Paracentesis involves the removal of ascitic fluid from the abdominal cavity with a needle or a catheter. Although paracentesis can remove large amounts of ascitic fluid (e.g., 10 L), removal of as little as 1 L of fluid may provide considerable relief from the painful stretching of skin and the respiratory distress that occurs with massive ascites. The ascitic fluid often re-accumulates rapidly after paracentesis.

The major complications of overly aggressive, large-volume paracentesis include hypotension, shock, oliguria, encephalopathy, and renal insufficiency. Other potential complications of paracentesis are hemorrhage, perforation of the abdominal viscera, infection, and protein depletion.[38]

ALBUMIN

CASE 25-1, QUESTION 10: R.W. continues to re-accumulate ascitic fluid and is exhibiting signs of declining renal function. A 6-L paracentesis coupled with a 50-g albumin infusion is ordered. Why are albumin infusions used in conjunction with paracentesis?

Large-volume (>4 L) paracentesis should be performed for patients with tense ascites, resulting in respiratory distress or impaired ambulation. However, large-volume paracentesis is associated with paracentesis-induced circulatory dysfunction (PICD), which manifests clinically as worsening renal function 24 to 48 hours post-procedure.[72,73] Intravenous (IV) albumin infusions are commonly administered to prevent PICD after large-volume paracentesis.[38] Use of albumin in combination with large-volume paracentesis produces an expansion of circulating blood volume, increases cardiac output, and suppresses release of renin and norepinephrine.[73] Although albumin is costly and sometimes in short supply, for some patients it is appropriate with paracentesis.[74] In one study, patients requiring large-volume paracentesis (≥6 L/day) received either concomitant IV albumin (40 g) or saline. The incidence of PICD was significantly higher in the saline than the albumin group (33.3% vs. 11.4%, respectively). The prevalence of PICD after paracentesis depends on the volume of ascites removed such that albumin infusion may not be necessary for a single paracentesis <4 to 5 L.[38,74] For large-volume paracentesis greater than or equal to 6 L, 6 to 8 g of albumin is typically administered for each liter of ascites removed.[38]

Wilkes et al.[75] conducted a meta-analysis of 55 randomized, controlled trials evaluating the effects of albumin administration for a variety of indications on patient mortality. They found no improvement in mortality with albumin administration.[75] However, albumin administered to patients with spontaneous bacterial peritonitis lowered the incidence of renal impairment (10% vs. 33%; $p = 0.002$), overall mortality at 3 months (22% vs. 41%; $p = 0.03$), and hospital mortality (10% vs. 29%; $p = 0.01$) than the group that did not receive albumin.[76]

DEXTRAN 70 AND OTHER PLASMA EXPANDERS

The use of synthetic plasma expanders with large-volume paracentesis has also been explored in patients with refractory ascites.[77] Gines et al.[78] studied patients with ascites refractory to diuretic therapy, who required paracentesis. More patients treated with dextran 70 (34.4%) or polygeline (37.8%) experienced PICD than those receiving albumin (18.5%).[78] Hydroxyethyl starch, an effective colloid agent for intravascular volume expansion, should not be used in patients with cirrhosis, because repeated administration in this population has been reported to accumulate in the hepatocytes, causing severe portal hypertension and acute liver failure.[79]

R.W. should be given 50 g of 25% albumin administered at a rate of 3 mL/minute, for the 6 L of ascitic fluid removed. Albumin 25% infusion is preferred because 5% solution has fivefold the sodium load.[38] More rapid administration than 3 mL/minute in hypoproteinemic patients can cause circulatory overload and pulmonary edema. R.W. should be monitored for anaphylactic reactions (rare), hypotension, hypertension, and signs of pulmonary edema.[80–82]

Alternative Therapy

CASE 25-1, QUESTION 11: What alternative treatments are available for management of refractory ascites? How would these alternatives be applied in R.W.'s case?

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT

Transjugular intrahepatic portosystemic shunt (TIPS) is another option for patients who are refractory to the pharmacologic interventions described previously. It is a nonsurgical technique for establishing a shunt in patients with portal hypertension (Fig. 25-2).[83] The TIPS procedure involves opening a conduit between the hepatic vein and the intrahepatic segment of the portal vein with an expandable metal stent placed during an angiographic procedure. This low-resistance channel allows blood to return to the systemic circulation and reduces portal pressure. In addition, TIPS may improve urinary sodium excretion. The major complications of TIPS include severe encephalopathy and shunt occlusion. Hepatic encephalopathy (see Case 25-3) occurs in approximately 20% of patients after TIPS.[83] Because of poor prognosis, liver transplantation should be considered for appropriate candidates refractory to pharmacologic treatment and/or shunt placement.[38] Selection of surgical shunt procedures may include evaluation of liver transplantation candidacy because some procedures may complicate the feasibility of a future liver transplantation procedure.

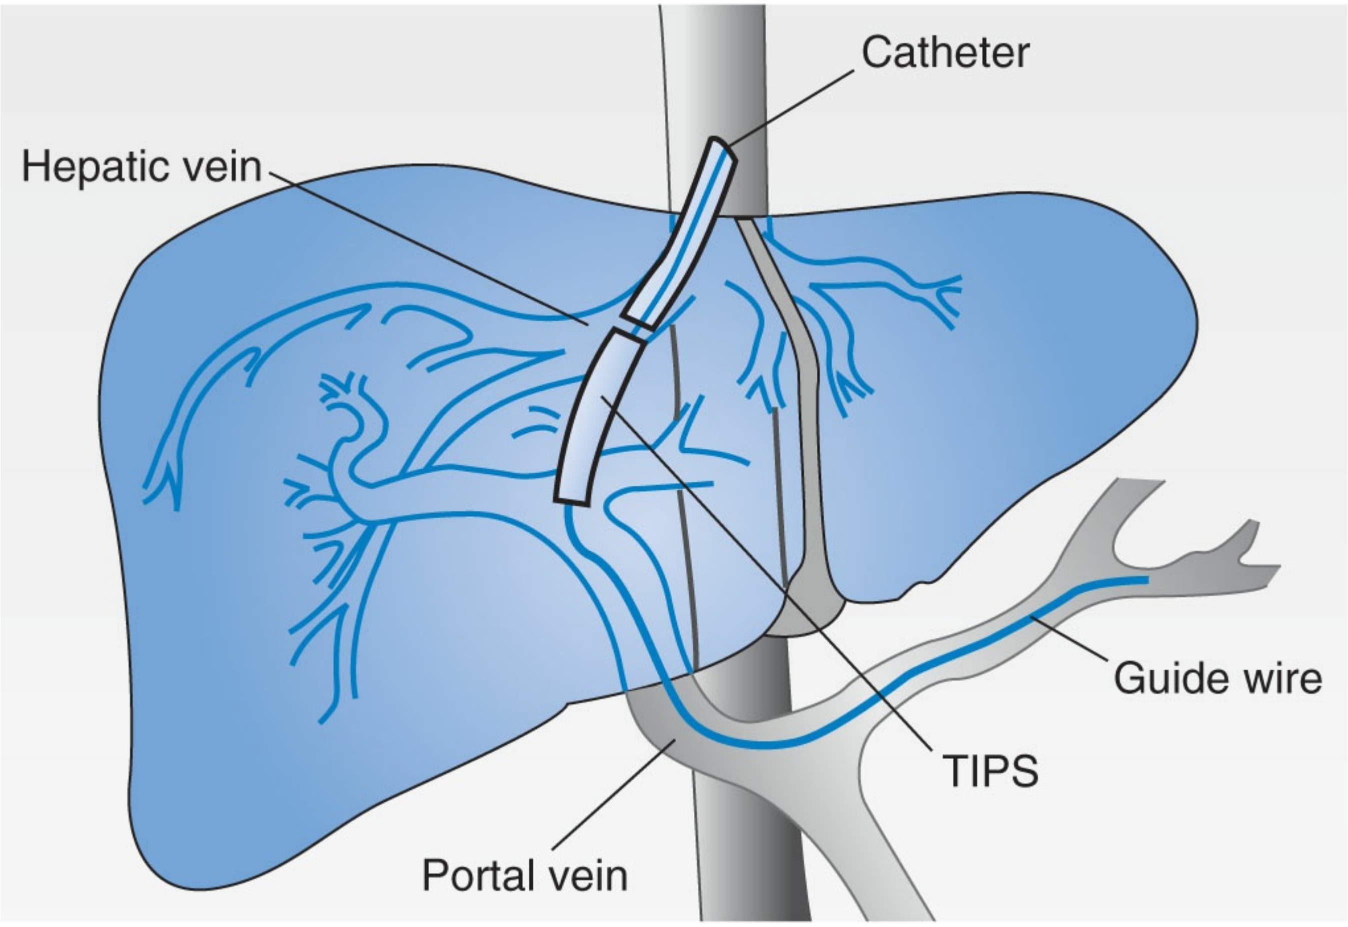

Figure 25-2 Transjugular intrahepatic portosystemic shunt (TIPS). A stent is inserted via catheter to the portal vein to divert blood flow and reduce portal hypertension. (Adapted with permission from Smeltzer SC, Bare BG. Textbook of Medical-Surgical Nursing. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2000.)

In a small randomized study evaluating patients with cirrhosis and refractory ascites,[84] the probability of survival without liver transplantation was 41% at 1 year and 26% at 2 years in the TIPS group, as compared with 35% and 30%, respectively, in the paracentesis group (not significant [NS]). Recurrence of ascites and development of hepatorenal syndrome (49% and 9%, respectively) were lower in the TIPS group compared with the paracentesis group (83% and 31%, respectively; $p = 0.003$ and $p = 0.03$), whereas the frequency of severe hepatic encephalopathy was greater in the TIPS group ($p = 0.03$). The calculated costs of procedures performed per patient in the TIPS group were 103% greater than those in the paracentesis and albumin group.[84] Salerno et al.[85] conducted a meta-analysis of cirrhotic patients with refractory ascites and found that transplant-free survival was higher in the TIPS group (38.1% vs. 28.7% at 3 years; $p = 0.035$), and the recurrence of ascites was lower (42% vs. 89%; $p < 0.0001$) than in the large-volume paracentesis group. The average number of hepatic encephalopathy episodes was significantly higher in the TIPS group ($p = 0.006$). However, the probability of developing the first episode of hepatic encephalopathy was similar between the groups ($p = 0.19$).[85]

The AASLD guidelines mention that as the level of experience as well as technology with TIPS improves, the outcomes associated with TIPS in future trials may also improve.[38] Currently, the AASLD treatment guidelines continue to recommend TIPS for the treatment of refractory ascites in patients for whom paracentesis is contraindicated, ineffective as determined by the frequency of repeated paracentesis (more than 3 times per month), or intolerant of repeated large-volume paracentesis.[86]

PERITONEOVENOUS SHUNT

A peritoneovenous shunt consists of a surgically implanted valve in the abdominal wall, an intra-abdominal cannula, and an outflow tube tunneled subcutaneously from the valve to a vein that empties directly into the superior vena cava. In this manner, ascitic fluid can be withdrawn from the abdominal cavity and be returned to the vascular space. Multiple contraindications exist to surgical shunts and significant surgical risks increase in likelihood with worsening hepatic function.[87] The lack of survival benefit, surgical complications, including fibrous adhesions complicating future liver transplantation, and the high risk of shunt occlusion have led to the reserving of peritoneovenous shunt procedures for patients with refractory ascites that are not candidates for paracentesis, liver transplantation, or TIPS.[38]

CLONIDINE

It has been shown that the activation of the sympathetic nervous system leads to renal hypoperfusion and sodium retention. The activated sympathetic nervous system stimulates renal α_1-adrenoreceptors and causes decreases in renal blood flow and glomerular filtration rate. Additionally, norepinephrine increases proximal tubular reabsorption of sodium and enhances renin, aldosterone, and vasopressin secretions.[88–90] Preliminary evidence suggests that clonidine may be of benefit in refractory ascites and an activated sympathetic nervous system. Lenaerts et al.[91] conducted a very small study in patients randomly assigned to receive repeated large-volume paracentesis (4–5 L every 48 hours) plus IV albumin (7 g/L ascites) until ascites disappeared, or a combination of clonidine 0.075 mg BID for 8 days and then clonidine 0.075 mg BID with spironolactone 200 to 400 mg daily for 10 days. Both groups were discharged with spironolactone adjusted according to individual response. During the first hospitalization, the mean weight loss in the paracentesis group was higher than in the clonidine group, but the mean hospital stay was shorter in the clonidine group ($p \leq 0.01$). Clonidine decreased sympathetic activity and increased glomerular filtration rate. During the follow-up, the number of re-hospitalizations for ascites was higher and the mean time to the first readmission was shorter in the paracentesis group than in the clonidine group ($p \leq 0.01$).[91] In another trial, Lenaerts et al.[90] found that the time to first readmission for tense ascites was shorter in the placebo group than in the clonidine group. Both groups received spironolactone and furosemide.[90] The addition of clonidine to diuretic therapy may be an effective therapeutic modality; however, a large randomized trial is needed to establish the role of clonidine in the treatment of ascites. Currently, the use of clonidine is considered experimental by the AASLD guidelines.[38]

In consideration of R.W.'s increasing serum creatinine concentration, rising BUN, and the grave prognosis of hepatorenal syndrome, TIPS is a reasonable therapeutic alternative if R.W. cannot tolerate or requires frequent large-volume paracentesis. Patients with a history of spontaneous bacterial peritonitis (SBP) and ascites with advanced liver failure or renal impairment appear to benefit from SBP prophylaxis. R.W. would benefit from the addition of SBP prophylaxis because of his history of SBP (see Chapter 70, Intra-Abdominal Infections).

ESOPHAGEAL VARICES

Treatment

CASE 25-2

QUESTION 1: C.V., a 55-year-old, pale-looking woman with alcohol-induced cirrhosis, was admitted for a chief complaint of hematemesis. C.V. has a history of recurrent upper GI bleeding and documented esophageal varices. She has no other significant medical history. She is not taking any medications and has no known drug allergies. On examination, her blood pressure (BP) was 78/40 mm Hg, pulse rate was 110 beats/minute, and respiratory rate was 22 breaths/minute. Her skin was cold; chest and cardiac examinations were within normal limits and abdominal examination revealed ascites and a palpable spleen. Bowel sounds were normal. Laboratory values included the following:

Hgb, 7 g/dL
Hct, 22%
Albumin, 3.0 g/dL
AST, 160 IU
ALT, 250 IU
Alkaline phosphatase, 40 IU
Creatinine, 2.0 mg/dL
PT, 18 seconds (INR, 1.5)
Serum electrolytes, all within normal limits

An electrocardiogram revealed sinus tachycardia. What are the immediate goals of therapy and treatment measures of the highest priority in managing C.V.'s hematemesis?

GOALS OF THERAPY

Most patients with cirrhosis develop portal hypertension, which in turn can progress to bleeding varices (dilated veins in the upper GI tract that protrude into the esophageal or gastric lumens). Of patients with Child–Turcotte–Pugh class A cirrhosis, 40% develop esophageal varices, as compared with 85% of those with Child–Turcotte–Pugh class C.[24,92] Unless varices bleed, they do not cause significant complications or symptoms.

The progression and severity of varices is directly related to the severity of portal hypertension. The major site of concern in portal hypertension is the coronary vein, draining the bottom of the esophagus and upper stomach. The scarring and fibrosis associated with cirrhosis initially leads to an increase in portal vein pressure (PVP), which may eventually rise, causing backflow of blood supply and subsequent increased pressure in the veins coming off the portal vein. Hyperkinetic circulation in the branches of the portal vein raises the esophageal trans-mural pressure and increases the risk of upper GI bleeding. Because the veins are designed for low-pressure circulation (5–8 mm Hg) and generally cannot tolerate a sustained hyperdynamic circulation, the shunting of high portal pressure blood results in gastric and esophageal varices. When PVP exceeds 12 mm Hg, patients are at increased risk of variceal hemorrhage.[93]

Varices can only be visualized during a diagnostic endoscopy. Esophageal varices are graded as small or large (>5 mm). The presence or absence of red signs (red wale marks or red spots) on varices is also noted.[92]

Despite improvement in the management of portal hypertension, massive bleeding from esophageal or gastric varices is the leading cause of death in patients with cirrhosis.[94] Prevention of variceal bleeding is critical because the mortality rate remains at 32% in Child–Turcotte–Pugh class C patients.[94] New varices develop at a rate of 5% to 10% per year in cirrhotic patients. Once varices develop, they enlarge by 4% to 10% each year.[95] Acute variceal bleeding is considered a medical emergency and should be treated immediately. Treatment goals include volume resuscitation, acute treatment of bleeding, and prevention of recurrence of variceal bleeding. Approximately 10% to 20% of patients are refractory to endoscopic and medical intervention and may require life-saving portal decompressive shunt surgery or TIPS.[24]

GENERAL MANAGEMENT

Resuscitation is the first priority in patients with acute bleeding episodes. An indwelling nasogastric tube (NG) should be placed, then saline or tap-water lavage of the stomach, with suctioning of the gastric contents, should be initiated promptly to prevent airway complications such as aspiration pneumonia.[83,96] Obtunded or unconscious patients should be intubated to maintain and protect the airway. Pharmacologic treatment should be initiated immediately to reduce bleeding and the risk of hypotension-induced renal failure. The patient should also be monitored for any abnormal electrolyte and metabolic chemistries (e.g., potassium, sodium, bicarbonate), hypoxia (e.g., Po$_2$, pH), serum creatinine, and decreased urinary output.[96]

Re-bleeding is most likely to occur within the first 2 to 5 days in patients with large varices and in patients with advanced liver disease (i.e., Child–Turcotte–Pugh class C, Table 25-1).[24,97] Factors associated with early re-bleeding include age greater than 60 years, acute renal failure, and severe initial bleeding defined by hemoglobin less than 8 g/dL at presentation. Risk factors for late re-bleeding are severe liver failure, continued alcohol abuse, large variceal size, renal failure, and hepatocellular carcinoma.[97]

HYPOVOLEMIA/BLOOD LOSS

Care should be taken when correcting hypovolemia so as not to increase the degree of portal hypertension by over-transfusion, which can increase the risk of further bleeding. Hypovolemia should be immediately managed to maintain a systolic blood pressure of 90 to 100 mm Hg and the hemoglobin at approximately 8 g/dL.[24,98] C.V.'s pallor, cold and clammy skin, rapid pulse, and a systolic BP less than 80 mm Hg suggest significant hypotension and hypovolemia needing correction with whole blood or packed red cell transfusion along with fresh frozen plasma.[92,97]

Patients with liver disease and elevated bilirubin frequently develop some level of vitamin K deficiency. Prolongation of the PT because of vitamin K deficiency usually improves within 24 hours after a 10 mg subcutaneous or oral dose of vitamin K (although evidence suggests parenteral repletion may be more reliable).[27] In contrast, a prolonged PT caused by poor liver function is not responsive to the administration of vitamin K. If the INR requires rapid correction because of bleeding or a planned invasive procedure, fresh frozen plasma should be transfused. Although vitamin K is often administered in the treatment of acute variceal bleeding, there is no data to support this practice.[99]

CASE 25-2, QUESTION 2: Three units of whole blood and two units of fresh frozen plasma were transfused initially. C.V.'s stomach was lavaged with saline, and the gastric aspirate from the NG tube continued to be strongly positive for blood. Four hours later, her bleeding still persisted. What other pharmacologic interventions can be used to control C.V.'s bleeding esophageal varices?

OCTREOTIDE

Octreotide is a synthetic analog of somatostatin, with similar pharmacologic properties and a slightly longer half-life. Somatostatin is available in Europe, but is substituted with octreotide or vapreotide (orphan drug status) in the United States (Table 25-2).[100–103] Octreotide is shown to be effective for controlling acute variceal bleeding and appears comparable in efficacy to vasopressin and balloon tamponade, with fewer side effects. Octreotide is administered as a 50 mcg bolus followed by an infusion of 50 mcg/hour for 3 to 5 days.[24] In one study, complete bleeding control was achieved in all patients receiving octreotide after 48 hours of therapy compared with 64% of vasopressin-treated patients, and 59% in the omeprazole groups ($p < 0.005$). Patients receiving vasopressin also experienced more side effects (abdominal cramps, nausea, tremor, decreased cardiac output, myocardial ischemia, and bronchial constriction) than those receiving octreotide or omeprazole ($p < 0.01$). In the patients with bleeding not controlled within 48 hours in the vasopressin and omeprazole groups, complete bleeding control was subsequently achieved by octreotide.[104] In a meta-analysis of octreotide and somatostatin versus vasopressin in the management of acute esophageal variceal bleeds, octreotide and somatostatin appeared to be more effective in controlling acute bleeding (82% vs. 55%; p = NS) and had fewer adverse effects requiring discontinuation than vasopressin (0% vs. 10%; p = 0.00007).[105] In general, octreotide is fairly well tolerated.[104] Although some centers may still initiate therapy with vasopressin, most will use octreotide as first-line therapy and reserve vasopressin for treatment failures.

VASOPRESSIN

Vasopressin, a naturally occurring hormone (also known as 8-arginine vasopressin, ADH), is produced by the posterior pituitary and was originally derived for the treatment of diabetes insipidus in persons with pituitary insufficiency.[100,101] Its use to control variceal bleeding is a non-FDA-labeled use that takes advantage of its intense smooth muscle vasoconstrictive properties. Vasopressin (Table 25-2) is effective in reducing or terminating bleeding in approximately 60% of patients with variceal hemorrhage.[100,101] Of concern are reports of patients developing hypertension, angina, arrhythmias, and, rarely, myocardial infarction while receiving vasopressin. Vasopressin is given as a continuous IV infusion because of its short half-life. To minimize dose-related adverse effects, the lowest effective dosage should be used. Vasopressin may be administered by peripheral IV infusion, but use of a central vein is preferred because of the risk of tissue necrosis if extravasation occurs. Most commonly, vasopressin is initiated as a continuous IV infusion of 0.2 to 0.4 units/minute, and increased every hour by 0.2 units/minute until control of bleeding is obtained (maximal dose 0.8 units/minute).[92] Approximately 12 hours after the control of bleeding, the infusion rate can be decreased by half. Higher doses should be avoided because dosages exceeding 1 unit/minute fail to control hemorrhage in patients who are unresponsive to lower dosages.[106] Because of the potential for serious cardiovascular and dermatologic complications caused by nonspecific vasoconstriction, vasopressin should be used only when necessary and for a duration necessary to control bleeding. The duration of infusion should not exceed 24 hours.[92] Interestingly, a meta-analysis of four randomized controlled trials comparing vasopressin for the acute treatment of variceal bleeding with non-active treatment or placebo found no difference in mortality.[100] Since efficacy of vasopressin for treatment of esophageal bleeding is limited and adverse effects (e.g., abdominal cramping, arrhythmias, and gangrene) are of great concern (Table 25-2), it has largely been replaced by octreotide. Nonetheless, some clinicians still prescribe vasopressin.

Nitroglycerin can help to minimize the adverse vascular and cardiac effects of vasopressin and enhance the reduction in portal pressure. When given by IV infusion, the nitroglycerin dosage is 40 to 200 mcg/minute.[100,102,107] A randomized trial by Gimson et al.[108] found a lower rate of complications in the vasopressin and nitroglycerin group compared with vasopressin alone. At the end of the 12-hour study period, variceal hemorrhage was controlled in 68% receiving combined therapy versus 44% in those given vasopressin alone ($p < 0.05$). Major complications requiring cessation of therapy were less common in those given nitroglycerin compared with those given vasopressin alone ($p < 0.02$).[108]

TERLIPRESSIN

Terlipressin, a synthetic analog of vasopressin and a pro-drug of lypressin (currently not available in the United States), effectively controls acute bleeding from esophageal varices in 80% of patients. Fewer cardiovascular side effects have been associated with terlipressin than with vasopressin.[109] Octreotide, vapreotide, vasopressin, and terlipressin have been shown to be effective in the control of acute variceal hemorrhage.[110,111] Terlipressin, however, is the only medication for the acute treatment of variceal hemorrhage that has been shown to improve patient survival. In a meta-analysis of seven randomized, placebo-controlled trials, terlipressin led to significant reductions in mortality as compared with placebo (relative risk [RR], 0.66; 95% CI, 0.49–0.88).[112]

Table 25-2

Treatment of Acute Bleeding

Therapy	Mechanism	Side Effects and Risks
Octreotide	Selective and potent vasoconstrictor that reduces portal and collateral blood flow by constricting splanchnic vessels	Diarrhea, hyperglycemia, hypoglycemia, constipation, rectal spasms, abnormal stools, headache, dizziness, fat malabsorption
Vasopressin	Nonspecific vasoconstrictor of all parts of the vascular bed	Abdominal cramping, nausea, tremor, skin blanching, phlebitis, hematoma at the site of the infusion, worsening of hypertension, angina, arrhythmias, myocardial infarction, bowel necrosis, gangrene, dilutional hyponatremia
Endoscopic variceal ligation (EVL)	An elastic band is placed around the mucosa and submucosa of the esophageal area containing the varix, leading to strangulation, fibrosis, and ideally obliteration of the varix	Moderate bleeding, hypotension, gastrointestinal discomfort, esophageal ulceration, perforation
Sclerotherapy	Injection of 0.5–5 mL of a sclerosing agent (e.g., concentrated saline: 11.5% NaCl or ethanolamine oleate) into each varix at points	Esophageal ulceration, stricture formation, esophageal perforation, retrosternal chest pain, temporary dysphagia

	about 2 cm apart to induce immediate hemostasis (cessation of bleeding within 2 to 5 minutes)	
Balloon tamponade	Bleeding is controlled by direct compression of the varices at the gastroesophageal junction or at the bleeding site by a Sengstaken–Blakemore tube or Linton tube (gastric varices only). The tube is passed through the mouth and into the stomach. A balloon is then inflated, which applies direct compression to the varices	Aspiration (>10% incidence), pressure necrosis, pneumonitis, esophageal ulceration and rupture, bleeding on balloon deflation, chest pain, asphyxia (aspiration may be minimized by endotracheal intubation and continued aspiration of oropharyngeal secretions)
Transjugular intrahepatic portal systemic shunt (TIPS)	A conduit between the hepatic vein and the intrahepatic segment of the portal vein with an expandable metal stent is placed during an angiographic procedure. This channel allows blood to return to the systemic circulation and reduces portal pressure	Bleeding, thrombosis, stenosis, severe encephalopathy, hepatic failure, shunt occlusion, shunt migration

Longer treatment with vasoactive drugs to prevent early variceal re-bleeding in cirrhosis. Eur J Gastroenterol Hepatol. 1998;10:1041.

Pharmacologic therapy for C.V. (somatostatin or its analogs [octreotide or vapreotide] or terlipressin) should be initiated as soon as variceal hemorrhage is suspected and continued for 3 to 5 days after diagnosis is confirmed.[92]

ENDOSCOPIC VARICEAL LIGATION AND SCLEROTHERAPY

CASE 25-2, QUESTION 3: Octreotide and vasopressin are nonspecific vasoconstrictors that require continuous IV infusion and carry a risk of systemic side effects. What is the place of endoscopic variceal ligation and sclerotherapy in the management of C.V.'s hemorrhage? What is a balloon tamponade? Are alternative therapies such as TIPS appropriate?

After successful resuscitation, endoscopy should be performed within 12 hours to establish the cause of bleeding.[92] Fiberoptic endoscopy allows direct visualization of the esophagus and location of the bleeding. Those with actively bleeding varices can be treated with endoscopic variceal ligation (EVL), sclerotherapy, or balloon tamponade. EVL is a well-tolerated procedure (Table 25-2).[110,113–117] Villanueva et al.,[118] in a randomized, controlled trial, found that the use of variceal ligation instead of sclerotherapy had a lower failure rate (4% vs. 15%; $p = 0.02$) and a lower transfusion requirement ($p = 0.05$). No statistically significant differences were found in mortality. Adverse effects (e.g., aspiration pneumonia, esophageal bleeding, ulceration, and chest pain) occurred in 28% of patients receiving sclerotherapy and

14% with ligation (RR, 1.9; 95% CI, 1.1–3.5; $p = 0.03$).[118] In another similar but smaller study, Sarin et al.[119] found that the rate of re-bleeding was lower in the EVL group than in the sclerotherapy group (6.4% vs. 20.8%; $p < 0.05$). EVL is the recommended form of therapy for acute esophageal variceal bleeding, although sclerotherapy may be used in the acute setting if ligation is technically difficult. Endoscopic treatments are best used in combination with pharmacologic therapy, which preferably should be started before endoscopy.[111] The AASLD Practice Guidelines Committee and the Practice Parameters Committee of the American College of Gastroenterology (ACG) on the Prevention and Management of Gastroesophageal Varices and Variceal Hemorrhage in Cirrhosis recommend that for the control and management of acute hemorrhage, the combination of vasoconstrictive pharmacologic therapy and variceal ligation is the preferred approach.[92] Therefore, C.V. should immediately be treated with octreotide for 3 to 5 days, and EVL to control the esophageal variceal bleeding.[24,92]

BALLOON TAMPONADE

Balloon tamponade is used to control bleeding by direct compression to the site of origin in massive hemorrhage cases (Table 25-2). It is important to remember that balloon tamponade is only a temporary measure and can cause pressure necrosis after 48 to 72 hours. Thus, the balloon should be deflated after 12 to 24 hours. Deflation and removal of the tube can result in removal of the fibrin scab at the bleeding site, resulting in re-bleeding. Balloon tamponade will achieve temporary control of the bleeding and allow time for other measures (e.g., EVL or sclerotherapy) to be undertaken.[92,110,120,121]

ALTERNATIVE TREATMENT MODALITIES

Transjugular Intrahepatic Portal Systemic Shunt

Although the combination of pharmacotherapy (octreotide, terlipressin, or somatostatin) and endoscopic procedures (EVL or sclerotherapy) has been shown to be beneficial in controlling acute bleeding, re-bleeding episodes can occur.[92,110] Poor responders to initial therapy may require further intervention to lower portal pressure and control the bleeding.

Henderson et al.[122] conducted a prospective, multicenter trial comparing distal splenorenal shunt (DSRS) to TIPS for variceal bleeding refractory to medical treatment with β-blockers and endoscopic therapy. Patients with Child–Turcotte–Pugh class A and class B cirrhosis and refractory variceal bleeding were randomly assigned to DSRS or TIPS. No significant differences were found in survival at 2 and

5 years (DSRS, 81% and 62%; TIPS, 88% and 61%, respectively). Thrombosis, stenosis, and re-intervention rates were significantly higher in the TIPS group (DSRS, 11%; TIPS, 82%; $p < 0.001$). Re-bleeding, encephalopathy, ascites, need for transplantation, quality of life, and costs did not significantly differ between groups.[122] TIPS has the advantage of being less invasive and faster than surgical portal systemic shunts. Long-term patency of the TIPS remains problematic (Table 25-2). TIPS can be used as a bridge to liver transplantation, and might be an effective option for nonsurgical patients or those with advanced cirrhosis (Child–Turcotte–Pugh class C) with recurrent bleeding, uncontrolled by pharmacologic and endoscopic therapy.[86,92,110,123,124] TIPS would be an option for C.V. if EVL and pharmacologic therapy fail.

Surgery

Surgical creation of a portacaval shunt has been effective in reducing portal pressure and in preventing recurrent bleeding. These shunts, however, are associated with a high incidence of hepatic encephalopathy and may exacerbate hepatic parenchymal dysfunction by shunting blood away from the liver. Mesocaval shunts and distal splenorenal shunts are also effective in preventing variceal re-bleeding and may be associated with a lower incidence of hepatic encephalopathy.[125]

INFECTION PROPHYLAXIS: SHORT-TERM ANTIBIOTICS

CASE 25-2, QUESTION 4: Should C.V. receive prophylaxis for bacterial infections?

Variceal hemorrhage is a risk factor for the development of severe bacterial infections, which increase mortality.[92] Short-term administration of antibiotics for the prevention of bacterial infections in patients with variceal hemorrhage has demonstrated favorable results.[126,127] In a prospective, randomized trial comparing norfloxacin 400 mg BID for 7 days ($n = 60$) with no treatment controls ($n = 59$), the norfloxacin group had a significantly lower incidence of spontaneous bacterial peritonitis (SBP, 3.3% vs. 16.9%; $p < 0.05$); although the decrease in mortality (6.6% vs. 11.8%) did not reach statistical significance.[126] Because of the emergence of infections caused by quinolone-resistant bacteria, Fernandez et al.[127] compared oral norfloxacin versus IV ceftriaxone in the prophylaxis against bacterial infection in cirrhotic patients with GI hemorrhage. Patients were randomly assigned to oral norfloxacin 400 mg BID or IV ceftriaxone 1 g/day for 7 days. Antibiotics were initiated after emergency endoscopy and within 12 hours of hospital admission. The probability of developing proven infections (26% vs. 11%; $p < 0.03$), and bacteremia or spontaneous bacterial peritonitis (12% vs. 2%, $p < 0.03$) was significantly higher in patients receiving norfloxacin as compared with ceftriaxone. No significant difference was seen between groups in mortality at 10 days.[127] A Cochrane review of 12 trials evaluating the role of antibiotic prophylaxis with placebo or no antibiotic prophylaxis to prevent bacterial infections in cirrhotic patients with upper gastrointestinal bleeding reported that antibiotic prophylaxis was associated with a significant decrease in mortality from bacterial infections (RR, 0.43; 95% CI, 0.19–0.97).[128]

The AASLD guidelines recommend 7 days of antibiotic prophylaxis for prevention of SBP in patients with variceal hemorrhage with oral norfloxacin (400 mg BID) or ceftriaxone IV (1 g/day; when oral administration is not possible).[38] C.V. should be treated with norfloxacin 400 mg orally once daily (dose adjusted for creatinine clearance of 30 mL/minute), or ceftriaxone 1 g/day for 7 days to prevent SBP.

PRIMARY PROPHYLAXIS

CASE 25-2, QUESTION 5: All variceal hemorrhage interventions up to this point were aimed at terminating the acute bleeding episode. Could drug therapy have helped prevent the first episode of bleeding from C.V.'s esophageal varices?

Preventing the initial occurrence of variceal bleeding is referred to as primary prevention or primary prophylaxis. Pharmacologic prophylaxis is aimed at reducing the HVPG to $\leq$12 mm Hg, or a decrease from baseline of $\geq$20%.[129,130] In a small study by Vorobioff et al.,[129] none of the patients with HVPG $\leq$12 mm Hg bled from portal hypertensive-related causes as compared to 42% in the HVPG >12 mm Hg group. In addition, only one of the six patients with a HVPG less <12 mm Hg as compared with 16 (of 24) in the HVPG >12 mm Hg group died during the study period ($p < 0.06$).[129] In addition, Escorsell et al.[130] confirmed that a fall of HVPG by 20% or more from baseline was associated with a decreased risk of variceal bleeding (6% vs. 45%; $p = 0.004$).

β-Blockers

Nonselective β-adrenergic blockers decrease portal pressure through a reduction in portal venous inflow as a result of a decrease in cardiac output (β_1-adrenergic blockade) and splanchnic blood flow (β_2-adrenergic blockade). Only nonselective β-blockers have an adrenergic vasoconstrictive effect on mesenteric arterioles, resulting in a decrease in portal pressure. Usual starting dosages of propranolol are 10 mg 3 times a day, or nadolol 20 mg daily. Selective β-blockers (e.g., atenolol and metoprolol) have little effect on mesenteric arterioles and have not been shown to be effective in primary prophylaxis.[131]

Propranolol or nadolol, given in dosages to reduce the resting heart rate to 55 to 60 beats/minute or by 25%, have been shown to prevent or delay the first episode of variceal bleeding.[15] Nonselective

---

β-blockers are considered first-line drug therapy in the prevention of variceal hemorrhage based on numerous randomized, placebo-controlled trials and meta-analyses.[110,132] For example, Pascal et al.[133] conducted a prospective, randomized, multicenter, single-blinded trial of propranolol compared with placebo in the prevention of bleeding in patients with large esophageal varices without previous bleeding. Patients received either propranolol or placebo, with the endpoints of the study being bleeding and death. The dosage of propranolol was progressively increased to decrease the heart rate by 20% to 25%. The cumulative percentages of patients free of bleeding 2 years after inclusion in the study (74% vs. 39%; $p < 0.05$) and cumulative 2-year survival (72% vs. 51%; $p < 0.05$) were higher in the propranolol compared to the placebo group.[133]

Sarin et al.[134] conducted a prospective, randomized, controlled trial comparing EVL plus propranolol with EVL alone as primary prophylaxis for prevention of first variceal bleeding among patients with high-risk varices. The mean duration of follow-up for both groups was about 12.2 months (±10.7 months). EVL was performed at 2-week intervals until obliteration of varices. Propranolol was administered at a dosage sufficient to reduce heart rate to 55 beats/minute or 25% reduction from baseline, and continued after obliteration of varices. No significant differences were seen in the rates of bleeding and survival between groups, although more patients in the EVL alone group had recurrence of varices ($p = 0.03$).[134]

In a prospective, randomized, double-blind, placebo-controlled trial of propranolol for the primary prevention of variceal hemorrhage, Abraczinskas et al.[135] found that when propranolol was tapered off, the risk of variceal hemorrhage increased from 4% (while on propranolol therapy) to 24% (after propranolol withdrawal), and was comparable to the risk of bleeding in an untreated population (22% in the placebo group from the previous study). Importantly, patients who abruptly discontinued β-blockers experienced increased mortality compared with the untreated population (48% vs. 21%; $p < 0.05$).[135] Therefore, avoiding sudden discontinuation of β-blockers in this population is essential.

The AASLD/ACG guidelines recommend nonselective β-blockers for primary prophylaxis in patients with small varices that have not bled, but are at increased risk of hemorrhage (Child–Turcotte–Pugh class B or C or presence of red wale marks on varices). Patients with medium or large varices that have not bled but are at a high risk of hemorrhage (Child–Turcotte–Pugh class B or C or variceal red wale markings on endoscopy), nonselective β-blockers or EVL may be recommended. In contrast, patients with medium or large varices that have not bled and are not at the highest risk of hemorrhage (Child–Turcotte–Pugh class A patients and no red signs), nonselective β-blockers are preferred and EVL should be considered in patients with contraindications, intolerance, or noncompliance to β-blockers. The β-blocker should be titrated to the maximal tolerated dose.[92]

Isosorbide-5-Mononitrate

Isosorbide-5-mononitrate monotherapy for primary prophylaxis for variceal hemorrhage has not proven to be effective.[136,137] Garcia-Pagan et al.[137] conducted a prospective, multicenter, double-blind, randomized, controlled trial evaluating whether isosorbide-5-mononitrate prevented variceal bleeding in cirrhotic patients with gastroesophageal varices, who had contraindications or could not tolerate β-blockers. Patients received isosorbide-5-mononitrate or placebo. No significant differences were noted in the 1- and 2-year actuarial probability of bleeding or survival between the two treatment groups.[137]

When combined with a β-blocker, isosorbide-5-mononitrate caused a greater reduction in the hepatic venous pressure gradient than propranolol alone.[138] Merkel et al.[139] examined the value of combining nadolol and isosorbide-5-mononitrate for primary prevention of variceal bleeding. Patients in the nadolol monotherapy group received between 40 and 160 mg/day titrated to achieve a 20% to 25% decrease in resting heart rate. Patients in the combination group received nadolol and isosorbide-5-mononitrate 10 to 20 mg orally BID. The overall risk of variceal bleeding was 18% in the nadolol group compared with 7.5% in the combined treatment group ($p = 0.03$). However, a higher number of patients had to be withdrawn from the combination therapy group compared with the nadolol monotherapy group (eight vs. four patients) because of side effects.[139] The AASLD and ACG guidelines suggest that nitrates (either alone or in combination with β-blockers), shunt therapy, or sclerotherapy should not be used in the primary prophylaxis of variceal hemorrhage.[92]

Depending on the size of C.V.'s varices on endoscopy and the risk of hemorrhage, C.V. should have been given propranolol 10 mg 3 times a day or nadolol 20 mg daily titrated to reduce the resting heart rate to 55 to 60 beats/minute (or by 25%), or EVL to prevent or delay the first episode of variceal bleeding.

SECONDARY PROPHYLAXIS

CASE 25-2, QUESTION 6: C.V.'s hepatologist would like to start treatment to prevent further variceal hemorrhage. What are the long-term objectives for the treatment of C.V.? What treatment approaches can be used to prevent a recurrence of bleeding (secondary prevention)?

Secondary prevention or secondary prophylaxis is when therapy is used to prevent re-bleeding once it has occurred. All patients who survive a variceal bleeding episode should receive therapy to prevent recurrent episodes. It is important that the initiation of β-blockers be delayed until after recovery of the initial variceal hemorrhage. Initiation of a β-blocker during the treatment of an acute bleed would block the patient's acute tachycardia in response to his or her hypotension, which may adversely impact survival. The benefit of nonselective β-blockers in the prevention of re-bleeding episodes has been demonstrated by a number of trials.[113,140,141] For example, Colombo et al.[140] randomized cirrhotic patients with a history of variceal hemorrhage to propranolol, atenolol, or placebo. Oral propranolol was titrated until the resting pulse rate was reduced by ~25%, and atenolol was given at a fixed dose of 100 mg daily. The incidence of re-bleeding was significantly lower in patients receiving propranolol than those receiving placebo (p = 0.01). Bleeding-free survival was higher for patients on active drugs than for those on placebo (propranolol vs. placebo, p = 0.01; atenolol vs. placebo, p = 0.05).[140]

Eradication of varices by endoscopic procedures is also effective in preventing recurrent variceal bleeding.[15,141] A study by de la Pena et al.[141] showed that nadolol plus EVL (n = 43) reduced the incidence of variceal re-bleeding compared with EVL alone (n = 37). Variceal bleeding recurrence rate was 14% in the EVL plus nadolol group and 38% in the EVL alone group (p = 0.006). Mortality was similar in both groups and the actuarial probability of variceal recurrence at 1 year was lower in the EVL plus nadolol group than in the EVL alone group (54% vs. 77%; p = 0.06). The adverse effects in the β-blocker group were higher, and led to the withdrawal of 20% to 30% of the patients.[141]

A meta-analysis of randomized trials[142] reported that compared with EVL alone, EVL combined with β-blockers ± isosorbide mononitrate reduced overall re-bleeding (32% vs. 17%, respectively; p < 0.01) with no significant difference in mortality or complications. When comparing drug therapy alone to combination therapy with EVL and β-blockers ± isosorbide mononitrate, combination therapy showed a trend toward lower re-bleeding (29% vs. 37%, respectively; NS), but no effect on mortality. Combination therapy

---

with EVL plus β-blockers ± isosorbide mononitrate is effective in preventing re-bleeding. Drug therapy alone is an alternative.[142]

TIPS is an option for those patients who fail both EVL and prophylaxis with β-blocker therapy. In a randomized study of Child–Turcotte–Pugh class B and C cirrhotic patients surviving their first episode of variceal hemorrhage, Escorsell et al.[143] reported a lower rate of re-bleeding (13% vs. 39%; p = 0.007) and higher rate of encephalopathy (38% vs. 14%, p = 0.007) in patients treated with TIPS versus those treated with the combination of propranolol and isosorbide-5-mononitrate. The 2-year re-bleeding probability was also lower in the TIPS group (13% vs. 49%; p = 0.01). Of note, drug therapy improved the Child–Turcotte–Pugh class more frequently than with TIPS (72% vs. 45%; p = 0.04) and at lower costs.[143]

The AASLD/ACG guidelines suggest the use of a combination of nonselective β-blockers plus EVL for secondary prophylaxis. TIPS should be considered in patients who are Child–Turcotte–Pugh class A or B who experience recurrent variceal hemorrhage despite combination pharmacological and endoscopic therapy.[86,92]

Since C.V. has a history of recurrent upper GI bleeding, the best option to prevent further bleeding is to initiate a nonselective β-blocker and begin EVL. The β-blocker should be titrated to reduce the resting heart rate to 55 to 60 beats/minute or by 25%.

EVL should be repeated every 1 to 2 weeks until obliteration with a repeat endoscopy performed 1 to 3 months after obliteration and then every 6 to 12 months to check for variceal recurrence.[92] If this combination fails to prevent variceal hemorrhage, then TIPS would be considered as a therapeutic option.[86]

HEPATIC ENCEPHALOPATHY

CASE 25-3

QUESTION 1: R.C., a 57-year-old man, was admitted to the hospital because of nausea, vomiting, and abdominal pain. He had a long history of alcohol abuse, with multiple hospital admissions for alcoholic gastritis and alcohol withdrawal. Physical examination revealed a cachectic male patient (weighing 55 kg) with clouded mentation, who was not responsive to questions about name and place. Tense ascites and edema were noted, and the liver was percussed at 9 cm below the right costal margin. The spleen was not palpated, and no active bowel sounds were heard. Laboratory results on admission included the following:

Na, 132 mEq/L
K, 3.7 mEq/L
Cl, 98 mEq/L
Bicarbonate, 27 mEq/L
BUN, 24 mg/dL
SCr, 1.4 mg/dL
Hgb, 9.2 g/dL
Hct, 24.1%
AST, 520 IU
Alkaline phosphatase, 218 IU
Lactate dehydrogenase (LDH), 305 IU
Total bilirubin, 3.5 mg/dL
PT, 22 seconds (INR, 1.8)

A 70-g protein, 2,000-kcal diet was ordered. Furosemide 40 mg IV every 12 hours was ordered in an attempt to reduce the edema and ascites. Morphine sulfate and prochlorperazine were ordered for his abdominal pain and nausea, respectively. Two days after admission, R.C. had an episode of hematemesis. He became mentally confused and at times nonresponsive to verbal command. An NG tube was inserted and coffee-ground material was produced on continuous suctioning. Saline lavage was continued until the aspirate became clear. The next morning, R.C. was still in a confused mental state. He demonstrated prominent asterixis, and fetor hepaticus was noted on his breath. On the second day of his hospitalization, laboratory data were as follows:

Hgb, 7.4 g/dL
Hct, 21.2%
K, 3.1 mEq/L
SCr, 1.4 mg/dL
BUN, 36 mg/dL
PT, 22 seconds (INR, 1.8)
Guaiac positive stool

Hepatic encephalopathy and upper GI bleeding were added to his problem list.

What aspects of R.C.'s history are compatible with a diagnosis of hepatic encephalopathy? What classification of hepatic encephalopathy does he fall into?

Hepatic encephalopathy (HE) is a spectrum of central nervous system (CNS) abnormalities ranging from subclinical alterations to coma and caused by advanced liver disease and/or portosystemic shunting of blood. According to the guidelines by the American Association for the Study of Liver Diseases (AALSD) and the European Association for the Study of the Liver (EASL) for HE in Chronic Liver Disease, HE is classified according to four criteria: (1) underlying disease (Acute Liver Failure [Type A]; resulting from portosystemic bypass or shunting [Type B]; from cirrhosis [Type C]), (2) severity of manifestations, (3) according to time course (episodic, recurrent, or persistent HE), and (4) according to precipitating factors (nonprecipitated or precipitated).[144]

The gold standard to measure the severity of HE is by the West Haven Criteria (WHC), and patients with significant altered consciousness by the Glasgow Coma Scale (GCS). For more detail on WHC criteria and GCS, please refer to the AASLD/EASL 2014 guidelines at aasld.org (https://www.aasld.org/sites/default/files/guideline_documents/141022_AASLD_ The ISHEN (International Society for Hepatic Encephalopathy and Nitrogen Metabolism) consensus classifies patients as having Minimal Hepatic Encephalopathy (MHE) and Grade I hepatic encephalopathy (WHC) as Covert Hepatic Encephalopathy (CHE), whereas those with apparent clinical abnormalities as Overt Hepatic Encephalopathy (OHE). The ISHEN consensus defines the onset of disorientation or asterixis as the onset of OHE.[145] This chapter will focus on the treatment of OHE in cirrhosis.

During the early phase of HE, the altered mental state may present as a slight derangement of judgment, and change in personality, sleep pattern, or mood. Drowsiness and confusion become more prominent as the HE progresses. Finally, unresponsiveness to arousal and deep coma ensue. Asterixis, or flapping tremor, is often present in the early to middle stages of HE that precede stupor or coma.[144]

The clinical features (as seen in R.C.) include altered mental state and asterixis. He is classified as having OHE, Type C, Grade III, Episodic, Precipitated (by upper GI bleed; see Question 3).

Asterixis can be demonstrated by having the patient hyperextend his or her wrist with the forearms outstretched and fingers separated. It is characterized by bilateral, synchronous, repetitive arrhythmic motions occurring in bursts of one flap (twitch) every 1 to 2 seconds. Asterixis is not specific for HE and may also be present in uremia, hypokalemia, heart failure, ketoacidosis, respiratory failure, and sedative overdose.[144]

As discussed in the questions that follow, the pharmacologic management of HE is guided by both an understanding of the pathogenesis of this disorder and the stage of severity demonstrated by the individual patient. In most cases, HE is fully reversible; therefore, it is likely a metabolic or neurophysiologic rather than an organic disorder.[144] Severe, progressive HE can lead to irreversible brain damage (caused by increased intracranial pressure), brain herniation, and death.[144,146,147]

Pathogenesis

CASE 25-3, QUESTION 2: What is the pathogenesis of hepatic encephalopathy?

Several theories exist about the pathogenesis of HE. The most widely referenced theories involve abnormal ammonia metabolism; altered ratio of branched chain to aromatic amino acids; imbalance in brain neurotransmitters, such as γ-aminobutyric acid (GABA) and serotonin; derangement in the blood brain–barrier; and exposure of the brain to accumulated "toxins."[148] The pathogenesis of HE is likely multifactorial.

AMMONIA

Ammonia is a byproduct of dietary protein metabolism or digestion of protein-rich blood in the GI tract (e.g., from bleeding esophageal varices). Bacteria present in the GI tract digest protein into polypeptides, amino acids, and ammonia. These substances are then absorbed across the intestinal mucosa. Ammonia is readily metabolized in the liver to urea, which is then renally eliminated. However, when blood flow and hepatic metabolism are impaired by cirrhosis, serum and CNS concentrations of ammonia are increased. The ammonia that enters the CNS combines with α-ketoglutarate to form glutamine, an aromatic amino acid. Ammonia has been considered central to the pathogenesis of HE. An increased ammonia level raises the amount of glutamine within astrocytes, causing an osmotic imbalance, cell swelling, and ultimately brain edema. Although high serum ammonia and cerebrospinal glutamine concentrations are characteristic of encephalopathy, they may not be the actual cause of this syndrome.[147,149] According to the AALSD/EASL guidelines, high ammonia levels alone may not add any diagnostic, staging, or prognostic value. However, if a level is normal, the diagnosis of HE should be questioned. In the case where ammonia-lowering drugs are used (e.g., lactulose), repeated measurements of ammonia would be beneficial to assess their efficacy.[144]

AMINO ACID BALANCE

In both acute and chronic liver failure, the ratio of the branched chain to aromatic amino acids is altered. Because of the higher permeability of aromatic amino acid across the blood–brain barrier and into the cerebrospinal fluid, some aromatic compounds can lead to production of "false neurotransmitters" that can lead to hepatic encephalopathy with altered mental status (see Chapter 38, Adult Parenteral Nutrition).[148,149]

γ-AMINOBUTYRIC ACID

Schafer et al.[150] proposed that in liver disease, gut-derived GABA escapes hepatic metabolism, crosses the blood–brain barrier, binds to its postsynaptic receptor sites, and causes the neurologic abnormalities associated with HE. Others hypothesize that endogenous benzodiazepine-like substances, via their agonist properties, contribute to the pathogenesis of hepatic encephalopathy by enhancing GABA-ergic neurotransmission. The role of GABA and endogenous benzodiazepines in HE is still not clearly defined.[151,152]

Of all the toxins suspected to cause hepatic coma, ammonia and certain aromatic amino acids are most commonly studied. Other precipitating factors include infections, electrolyte disorders, GI bleeding, constipation, and over diuresis. These factors may increase the serum ammonia and precipitate an exacerbation of HE.[144,153,154]

CASE 25-3, QUESTION 3: What are the probable precipitating causes of hepatic encephalopathy in R.C.?

The main precipitating cause of HE in R.C. was the sudden onset of upper GI bleeding. The bacterial degradation of blood in the gut results in absorption of large amounts of ammonia and possibly other toxins into the portal system. Other important contributory factors in this case are diuretic-induced hypovolemia (BUN:SCr ratio >20), hypokalemia (potassium, 3.1 mEq/L), and potentially metabolic alkalosis (continuous NG suctioning and furosemide). Overzealous diuretic therapy increases HE by inducing pre-renal azotemia, hypokalemia, and metabolic alkalosis. Alkalosis promotes diffusion of nonionic ammonia and other amines into the CNS. The associated intracellular acidosis “traps” the ammonia by converting it back to ammonium ion (NH_4^+).[155,156]

Sedating drugs such as opioids (e.g., morphine, methadone, meperidine, codeine), sedatives (e.g., benzodiazepines, barbiturates, chloral hydrate), and tranquilizers (e.g., phenothiazines) can also precipitate HE. Encephalopathy precipitated by most drugs can be explained by increased CNS sensitivity and decreased hepatic clearance with subsequent drug and, in some cases, active metabolite accumulation. For R.C., the morphine and prochlorperazine might have contributed to the worsening of his HE. Although not applicable to this case, excessive dietary protein, infections, and constipation can also contribute to excess nitrogen load and hepatic coma.

Treatment and General Management

CASE 25-3, QUESTION 4: What nondrug steps should be taken to manage R.C.’s hepatic encephalopathy?

Correcting the precipitating factor underlying the episode of OHE can improve mental status in 90% of patients.[144] After identifying and removing precipitating causes of HE, therapeutic management is aimed primarily at reducing the amount of ammonia or nitrogenous products in the circulatory system. The 2013 ISHEN guidelines recommend an energy intake of 35 to 40 kcal/kg of body weight/day and a protein intake of 1.2 to 1.5 g/kg of ideal body weight/day for cirrhotic patients and those awaiting liver transplantation surgeries.[157–160] A study conducted by Cordoba et al.[161] randomized patients with cirrhosis and HE to two dietary groups for 14 days. The first group followed a progressive increase in the dose of protein receiving 0 g of protein for the first 3 days, then the protein was increased progressively every 3 days (12, 24, and 48 g) up to 1.2 g/kg/day for the last 2 days. The second group received 1.2 g/kg/day from the first day. Results showed that the course of HE was not significantly different between groups. The patients in the first group, however, experienced a higher degree of protein breakdown.[161]

R.C. is a cachectic male, and care should be taken in providing nutrition to malnourished patients. The 70-g protein, 2,000-kcal diet ordered for R.C. is appropriate because it falls within the recommended weight-based ranges established by the ISHEN guidelines. R.C. should be offered small meals or liquid nutritional supplements evenly distributed throughout the day along with a late-night snack.[157,158]

CASE 25-3, QUESTION 5: Which pharmacologic interventions are appropriate to manage R.C.'s hepatic encephalopathy?

LACTULOSE

Lactulose is broken down by GI bacteria to form lactic, acetic, and formic acids, which acidify colonic contents converting ammonia into the less readily absorbed ammonium ion. Back diffusion of ammonia from the plasma into the GI tract can also occur. The net result is a lower plasma-ammonia concentration. The absorption of other protein breakdown products (e.g., aromatic amino acids) may also be reduced. Lactulose-induced osmotic diarrhea decreases intestinal transit time available for ammonia production and absorption, and it may help clear the GI tract of blood. Lactulose syrup (10 g/15 mL) has been used successfully for the treatment of HE. For OHE, lactulose 25 mL is administered every 1 to 2 hours until catharsis occurs. Doses are then titrated downward to maintain 2 to 3 bowel movements daily and clear mentation in order to avoid complications of overuse of lactulose (aspiration, dehydration, severe perianal skin irritation, and precipitation of HE).[144] When the oral route of administration is not possible, as in the treatment of a comatose patient, it may be necessary to administer the drug through an NG tube. Alternatively, a rectal retention enema compounded with 300 mL of lactulose in 700 mL water can be prepared. The lactulose water mixture (125 mL) is retained for 30 to 60 minutes, although this is difficult in patients with altered mental status. The beneficial clinical effect of lactulose occurs within 12 to 48 hours. Patients may need long-term administration of lactulose as maintenance therapy, especially in patients with recurring HE. For prevention of recurrence of OHE, oral daily prophylactic dosing of lactulose should be maintained. If precipitating factors have been removed or liver function improved, prophylactic therapy may be tapered and potentially discontinued.[144] The administration of lactulose permits better dietary protein tolerance and is well tolerated if dosages are kept sufficiently low to avoid diarrhea.[162]

Although lactulose is the mainstay of HE treatment,[144,163] very limited data exist evaluating its efficacy. Care should be taken not to induce excessive diarrhea that could lead to dehydration and hypokalemia, both of which have been associated with exacerbation of HE. Although lactulose is generally well tolerated, 20% of patients may complain of gaseous distention, flatulence, or belching. Dilution with fruit juice, carbonated beverages, or water can reduce the excessive sweetness of the syrup.[146]

RIFAXIMIN

Rifaximin is a synthetic antibiotic structurally related to rifamycin. It has a wide spectrum of antibacterial activity against gram-negative and gram-positive bacteria, both aerobic and anaerobic.[164] Of note, 96.6% of the drug is recovered in the feces as unchanged drug, and what is absorbed undergoes metabolism with minimal renal excretion of unchanged drug.[82,165] It was introduced in the United States for the treatment of travelers' diarrhea,[166] but also is indicated for HE.[165] Although dosages used in HE trials ranged from 550 mg twice daily to 400 mg every 8 hours,[167,168] the FDA-approved dose for HE is 550 mg twice daily.[165] Rifaximin is well tolerated, but can cause flatulence, nausea, and vomiting. Some urticarial skin reactions have been reported with prolonged use.[169] Bacterial superinfections (Clostridium difficile—associated diarrhea) with >2 months of rifaximin have also been reported.[82,165]

NEOMYCIN

Neomycin is also an antibiotic effective in reducing plasma-ammonia concentrations (presumably by decreasing protein-metabolizing bacteria in the GI tract). Approximately 1% to 3% of the neomycin dose is absorbed. Chronic use in patients with severe renal insufficiency can cause ototoxicity or nephrotoxicity. Routine monitoring of serum creatinine, presence of protein in the urine, and estimation of creatinine clearance are advisable for patients receiving high dosages for more than 2 weeks.[162] Neomycin therapy can also produce a reversible malabsorption syndrome that not only suppresses the absorption of fat, nitrogen, carotene, iron, vitamin B_{12}, xylose, and glucose but also decreases the absorption of some drugs, such as digoxin, penicillin, and vitamin K.[146] Typical HE dosage for neomycin ranges from 500 to 1,000 mg 4 times daily, or as a 1% solution (125 mL) given as a retention enema (retained for 30–60 minutes) 4 times daily.[162]

FLUMAZENIL

Based on the theory of accumulation of endogenous benzodiazepine-like substances in HE, flumazenil, a benzodiazepine antagonist, has been evaluated for its role in the treatment of HE. Several trials have demonstrated both clinical and electrophysiologic improvement in patients with HE.[170] However, an IV product with modest benefits in the treatment of HE is not an ideal treatment option.

Lactulose versus Rifaximin

An extensive review of rifaximin for the treatment of HE conducted by Lawrence et al.[171] found that rifaximin was equally effective, and in some studies superior to lactulose in mild-to-moderate disease. Patients treated with rifaximin required fewer, shorter and less costly hospitalization than lactulose-treated patients.[171]

Bucci et al.[172] conducted a double-blind study comparing rifaximin (1,200 mg/day) and lactulose (30 g/day) for 15 days in patients with moderate to severe HE. After 7 days, ammonia concentrations normalized and at the end of the treatment period, cognitive function test scores improved in both groups. Rifaximin therapy was better tolerated.[172] Although the data reported from these and other trials suggest a benefit with rifaximin for the treatment of HE, larger trials must be conducted to determine its superiority over lactulose. In addition, the current cost of rifaximin is considerably higher than both lactulose and neomycin (estimated cash price: lactulose [60–100 g daily] ~$170–280/month; neomycin [500 mg 4 times daily] ~$220/month; and rifaximin [550 mg twice daily] ~$2,000/month; data per goodrx.com).

Rifaximin versus Neomycin

Miglio et al.[173] conducted a randomized, controlled, double-blind study to evaluate the efficacy and tolerability of rifaximin (400 mg 3 times daily) in comparison to neomycin (1 g 3 times daily) treatment for 14 days each month over 6 months. During the study, blood ammonia concentrations in both the rifaximin and neomycin groups decreased a similar amount.[173] Pedretti et al.[174] compared rifaximin 400 mg every 8 hours to neomycin 1 g every 8 hours in patients with cirrhosis and reported a higher rate of adverse events (increases in BUN, creatinine, nausea, abdominal pain, and vomiting) in the neomycin group after 21 days of therapy. Both drugs significantly decreased blood-ammonia concentrations. However, rifaximin produced an earlier reduction of blood ammonia.[174] Because of the lower adverse-effect profile and considerable efficacy, rifaximin has taken over as second-line therapy for HE over neomycin at many institutions.

Lactulose versus Neomycin

Orlandi et al.[175] found that lactulose and neomycin appear to have similar efficacy for the acute treatment of HE. However, in the treatment of an acute exacerbation, particularly in an acute GI bleed, lactulose may produce a faster response than neomycin.

Interestingly, although lactose therapy is considered the standard of practice in OHE treatment and prevention, a meta-analysis evaluating the efficacy of lactulose in patients with HE questions its benefit.[176] Large randomized, controlled trials are needed to determine the optimal treatment for HE management.[147] The AASLD/EASL guidelines consider neomycin as an alternative choice for treatment of OHE.[144]

Lactulose would be the preferred option to treat R.C.'s HE because it would shorten the time to clear the blood from his GI tract and hopefully lead to a rapid resolution of his confusion. Although neomycin is not contraindicated for R.C., the potential for worsening of his coagulopathy (by interfering with vitamin K absorption) and risk of nephrotoxicity (SCr, 1.4 mg/dL) make this a less optimal choice. If R.C.'s renal function continues to decline, neomycin may become contraindicated. Lactulose can be initiated at 25 mL every 1 to 2 hours until at least two soft or loose stools per day are produced. The dose can then be reduced to maintain 2 to 3 soft stools per day and improved mental status. R.C. may receive lactulose by NG tube if necessary in the early treatment period.

COMBINATION THERAPY WITH LACTULOSE

CASE 25-3, QUESTION 6: Would combination therapy provide any additive beneficial effect for R.C.?

A randomized, double-blind, placebo-controlled trial by Bass et al.[167] compared rifaximin versus placebo in the prevention of HE and hospitalization in patients recovering from recurrent HE (≥2 episodes within the previous 6 months). Patients were assigned to either rifaximin at a dose of 550 mg twice daily or placebo for 6 months. The study allowed the use of lactulose (approximately 90% of patients received concomitant therapy). The results of the study showed that a breakthrough episode of HE occurred in 22.1% with rifaximin and 45.9% with placebo. Hospitalization involving HE was lower with rifaximin (13.6%) than with placebo (22.6%). Adverse events were similar amongst the two groups.[167] The AASLD/EASL considers rifaximin as an effective add-on therapy to lactulose for prevention of OHE recurrence.[144] Previous HE guidelines (American College of Gastroenterology) stated that combination therapy of lactulose and neomycin may be reasonable in patients who do not respond to monotherapy.[162] The current AASLD/EASL guidelines do not address this combination.[144] R.C. would not benefit from combination therapy at this time.

HEPATORENAL SYNDROME

CASE 25-3, QUESTION 7: Lactulose treatment was initiated at 25 mL every hour and titrated to effect with some improvement in R.C.'s mental status. A few days after resolution of his GI bleeding, his serum creatinine increased from 1.4 to 2.7 mg/dL and he became progressively oliguric. His BP was 85/65 mm Hg, pulse rate was 70 beats/minute, and respiratory rate was 16 breaths/minute. Furosemide was discontinued, and R.C. was treated with albumin infusions to allow volume expansion and improve urine output. A renal ultrasound did not reveal any specific abnormalities. Minimal improvement occurred in his blood pressure and urine output. Laboratory results included the following:

Na, 123 mEq/L
K, 3.6 mEq/L
Cl, 98 mEq/L
Bicarbonate, 25 mEq/L
BUN, 96 mg/dL
SCr, 2.7 mg/dL
Hgb, 8.4 g/dL
Hct, 27.1%
AST, 640 IU
Alkaline phosphatase, 304 IU
LDH, 315 IU
Total bilirubin, 4.1 mg/dL
PT, 22 seconds (INR, 1.8)
A 24-hour urinalysis showed the following:
Protein, 50 mg/day
Red blood cells, 1 to 2 per high power field
Negative for WBC, glucose, and ketones

After exclusion of other possible causes of kidney disease, R.C. is diagnosed with hepatorenal syndrome. What are potential treatment options for R.C.'s hepatorenal syndrome?

Pathogenesis

Hepatorenal syndrome (HRS) is a complication of advanced cirrhosis characterized by an intense renal vasoconstriction, which leads to a very low renal perfusion and glomerular filtration rate, as well as a severe reduction in the ability to excrete sodium and free water.[177] Cárdenas et al.[178] summarized the pathogenesis and the precipitating factors of HRS, which can be found on nature.com (**http://www.nature.com/nrgastro/journal/v3/n6/fig_tab/ncpgasthep0517_F1.html** HRS is diagnosed by exclusion of other known causes of kidney disease in the absence of parenchymal disease. The revised criteria for the diagnosis of HRS as defined by the International Ascites Club (IAC) can be found at icascites.org (**http://www.icascites.org/about/guidelines/**).[179,180]

Hepatorenal syndrome can be classified into two categories. Type 1 HRS is characterized by an acute and progressive kidney failure defined by doubling of the initial serum creatinine concentrations to a level greater than 2.5 mg/dL in less than 2 weeks. Type 1 HRS is precipitated by factors such as SBP or large-volume paracentesis, but can occur without a precipitating event. This usually occurs within the setting of an acute deterioration of circulatory function characterized by hypotension and activation of endogenous vasoconstrictor systems. It may be associated with impaired cardiac and liver functions as well as HE. The prognosis of patients exhibiting type 1 HRS is very poor.[180,181] In contrast, type 2 HRS is a progressive deterioration of kidney function with a serum creatinine from 1.5 to 2.5 mg/dL. It is often associated with refractory ascites, and has a better survival rate than that of patients with type 1 HRS.[178,179,180]

Treatment

Treatments for HRS are still investigational. HRS is associated with a high mortality rate (within 2 weeks for type 1 HRS and 6 months for type 2 HRS). The definitive treatment for type 1 and type 2 HRS is liver transplantation, which is the only treatment that assures long-term survival.[68] The main goal of pharmacologic therapy is to manage HRS sufficiently so that the patient can survive long enough to obtain a suitable donor liver.[179,180] Diuretic therapy worsens HRS and should be discontinued.[178]

Solanki et al.[182] randomized patients with type 1 HRS to terlipressin 1 mg IV every 12 hours or placebo. Both groups also received albumin. Urine output, creatinine clearance, mean arterial pressures, and survival (42% vs. 0%) were significantly better with terlipressin than with placebo ($p < 0.05$). All survivors in the terlipressin group had a reversal of HRS.[182]

Sanyal et al.[183] conducted a prospective, double-blind, placebo-controlled clinical study in which patients with type 1 HRS were randomly assigned to terlipressin (1 mg IV every 6 hours) or placebo. If, after 3 days of therapy, the SCr level had not decreased by ≥30% from baseline, the dose was increased to 2 mg every 6 hours. All patients in this study also received albumin. The primary end point at day 14 was SCr ≤ 1.5 mg/dL on two occasions at least 48 hours apart, without dialysis, death, or recurrence of type 1 HRS. The primary end point was achieved twice as often with terlipressin than with placebo (25% vs. 12.5%,

---

respectively), although this did not reach statistical significance. In addition, terlipressin did not improve survival. However, terlipressin was superior to placebo for type 1 HRS reversal as defined by SCr ≤ 1.5 mg/dL (34% vs. 13%; $p = 0.008$). Adverse events were similar between groups.[183] In 2009, the FDA accepted the final section of the New Drug Application seeking marketing approval for terlipressin for the treatment of type 1 HRS, and granted priority review and fast-track designation.

In 2013, terlipressin was granted Orphan Drug Status.

Other nonrandomized studies suggest that vasoconstrictor therapy with norepinephrine (combined with albumin and furosemide) or midodrine (combined with octreotide and albumin) improve renal function in patients with type 1 HRS.[184–186] Esrailian et al.[187] conducted a retrospective chart review of type 1 HRS patients who received a combination of octreotide, midodrine, and albumin compared to untreated controls who received albumin only. Octreotide administration started at 100 mcg subcutaneously TID, with the goal to increase the dose to 200 mcg subcutaneous TID. Midodrine administration started at 5, 7.5, or 10 mg TID orally, with the goal to increase the dose to 12.5 or 15 mg if necessary. Adjustment in medication doses was based on a goal of increasing the mean arterial pressure by at least 15 mm Hg from baseline. All patients received intravenous expansion of plasma volume with 1.5 L of saline combined with an average of 120 g of human albumin after diuretic withdrawal. The authors found that at 30 days, 40% of treated patients had a sustained reduction in SCr, compared with 10% of the concurrent untreated controls ($p = 0.01$). In that same time period, 43% of patients in the treatment group had died, compared with 71% of controls ($p = 0.03$).[187]

Duvoux et al.[186] conducted a pilot study describing the efficacy and safety of norepinephrine in combination with IV albumin and furosemide in patients with type 1 HRS. Norepinephrine was given for 10 ± 3 days, at a mean dosage of 0.8 ± 0.3 mg/hour. Reversal of HRS was observed in 83% of patients after a median of 7 days, with a reduction in SCr (358 ± 161 to 145 ± 78 μmol/L; $p < 0.001$), a rise in creatinine clearance (13 ± 9 to 40 ± 15 mL/minute; $p = 0.003$), an increase in mean arterial pressure (65 ± 7 to 73 ± 9 mm Hg, $p = 0.01$), and a marked reduction in active renin and aldosterone plasma concentrations ($p < 0.05$).[186]

Two small, open-labeled, randomized, pilot studies evaluated the efficacy and safety of norepinephrine compared to terlipressin in the treatment of HRS.[188,189] All subjects also received albumin. Both drugs significantly improved renal function and had similar effects with respect to efficacy and safety. This preliminary data suggests that norepinephrine may be a safe, effective, and less costly alternative to terlipressin in the treatment of type 1 HRS. Further research is warranted.

The IAC guidelines recommend vasoconstrictors and albumin for first-line treatment of type 1 HRS. They advocate for the use of terlipressin (2–12 mg/day) in combination with albumin (20–40 g/day after 1 g/kg on the first day), and mention that about 60% of renal failure cases recover with this therapy. The IAC recommends midodrine (in addition to octreotide) and norepinephrine as two possible alternatives to terlipressin.[180] The latest AASLD recommendation is to consider the use of albumin plus octreotide and midodrine (largely because of the lack of availability of terlipressin in the United States).[38] Studies mention that the combination of both octreotide and midodrine are required to be effective.[190,191] The AASLD guidelines also recommend that albumin plus norepinephrine as a treatment option of type 1 HRS; however, this approach requires an intensive care unit.[38] Vasoconstrictor efficacy and safety requires further evaluation in large, randomized clinical trials.[184–186]

Type 2 HRS manifests itself as a progressive disease and, therefore, patients do not present acutely with deterioration in kidney function. No particular treatment exists for type 2 HRS. The main clinical problem in type 2 HRS is refractory ascites, which can be controlled by large-volume paracentesis along with IV albumin or TIPS.[178,184,192] Studies are needed to determine the place in therapy for vasoconstrictors and other potential treatments in patients with type 2 HRS.[180]

R.C. should continue to receive albumin 10 to 20 g IV per day, octreotide 100 mcg SC 3 times daily with a target dose of 200 mcg SC 3 times daily and midodrine 5 to 10 mg orally 3 times daily, with the goal to titrate up to 12.5 mg orally 3 times per day. The target increase in mean arterial pressure is 15 mm Hg.[38] Because of the poor prognosis associated with hepatorenal syndrome, R.C. should be evaluated for liver transplantation.

CASE 25-3, QUESTION 8: Why should liver transplantation be considered in patients with end-stage liver disease such as R.C.?

Liver transplantation for appropriate candidates may be the best option for end-stage liver disease and its complications leading to improved quality and duration of life. Transplantation is generally considered in patients with refractory ascites, severe hepatic encephalopathy, esophageal or gastric varices, and hepatorenal syndrome.[193] Because of the shortage of organs available and significant complications associated with transplantation, therapeutic alternatives should be considered to avoid the necessity for transplantation. For patients such as R.C., who are candidates for transplantation, therapeutic strategies to improve outcomes after transplantation should be considered in therapeutic decision-making before transplantation (see Chapter 34, Kidney and Liver Transplantation, for further information on the indications for liver transplantation).[192]

Acid–Base Disorders

Luis S. Gonzalez, III

CORE PRINCIPLES	CHAPTER CASES
① Acid–base analysis should proceed in a stepwise approach to avoid missing complicated disorders that may not be readily apparent.	**Case 26-1 (Question 1),** **Case 26-2 (Question 1),** **Case 26-3 (Question 1),** **Case 26-4 (Question 2),** **Case 26-5 (Question 3),** **Case 26-6 (Question 1)**
② A normal anion gap metabolic acidosis is most commonly found in patients who have either diarrhea or are receiving large amounts of isotonic crystalloid infusions. A less common cause of a normal anion gap metabolic acidosis occurs with patients who present with one of several types of renal tubular acidosis.	**Case 26-1 (Questions 2–6)**
③ A metabolic acidosis with an elevated anion gap is created by a disease process that produces an acid, which is buffered by the major extracellular buffer, bicarbonate. It is important to include a calculation of the anion gap in the workup of all patients considered for acid–base analysis.	**Case 26-2 (Questions 1–4)**
④ Metabolic alkaloses can be classified according to a patient's volume status and responsiveness to the administration of chloride-containing solutions. A contraction alkalosis, also called chloride-responsive alkalosis, is generally caused by diuretic administration whereas a chloride-nonresponsive alkalosis may be caused by glucocorticoid administration.	**Case 26-3 (Questions 1–4)**
⑤ A respiratory acidosis can be acute, chronic, or acute-on-chronic. The best way to differentiate these disorders is with a careful patient history and review of previous blood gas values looking for elevated carbon dioxide levels when a patient is at his or her baseline.	**Case 26-4 (Questions 1–4)**
⑥ Unlike respiratory acidosis, most patients presenting with a respiratory alkalosis do so acutely. There are a relatively small number of conditions that cause an acute respiratory alkalosis, which can aid in the diagnosis when it is not apparent.	**Case 26-5 (Questions 1–4)**
⑦ Mixed metabolic and respiratory acid–base disorders occur commonly in acutely ill patients. Acid–base analysis can assist in the diagnosis of	**Case 26-6 (Questions 1–3)**

clinically difficult cases. Following a stepwise approach in the analysis of acid–base disorders should identify all clinically important abnormalities.

Understanding the etiology of a clinically important acid–base disturbance is important because therapy generally should be directed at the underlying cause of the disturbance rather than merely the change in pH. Severe acid–base disorders can affect multiple organ systems, including cardiovascular (impaired contractility, arrhythmias), pulmonary (impaired oxygen delivery, respiratory muscle fatigue, dyspnea), renal (hypokalemia, nephrolithiasis), or neurologic (decreased cerebral blood flow, seizures, coma).

ACID–BASE PHYSIOLOGY

To protect body proteins, acid–base balance must be tightly controlled in an attempt to maintain a normal extracellular pH of 7.35 to 7.45 and an intracellular pH of approximately 7.0 to 7.3.[1] This narrow range is maintained by complex buffer systems, ventilation to expel carbon dioxide (CO_2), and renal elimination

of acids and reabsorption of bicarbonate (HCO_3^-).[2] At rest, about 200 mL of CO_2, and even more during exercise, is transported from the tissues and excreted in the lungs.[3] Although HCO_3^- is responsible only for about 36% of intracellular buffering, it provides about 86% of the buffering activity in extracellular fluid (ECF).[1] Extracellular fluid contains approximately 350 mEq of HCO_3^-, which buffers generated H^+.

$$HCO_3^- + H^+ \Leftrightarrow H_2CO_3 \qquad \text{(Eq. 26-1)}$$

Hydrogen ion (H^+) combines with HCO_3^- and shifts the equilibrium of Eq. 26-1 to the right. In the proximal renal tubule lumen, carbonic anhydrase catalyzes the dehydration of H_2CO_3 to CO_2 and H_2O, which are absorbed into the tubule cell, as illustrated in Eq. 26-2 and in Figure 26-1. Within the tubule cell, H_2O dissociates into H^+ and OH^-. The H^+ is then secreted into the lumen by a Na^+–H^+ exchanger. Carbonic anhydrase then catalyzes the combination of OH^- and CO_2 to HCO_3^-, which is carried into the circulation by a $Na^+HCO_3^-$ cotransporter.[4]

$$HCO_3^- + H^+ \Leftrightarrow H_2CO_3 \overset{CA}{\Leftrightarrow} CO_2\,(\text{dissolved}) + H_2O \qquad \text{(Eq. 26-2)}$$

To maintain acid–base balance, the kidney must reclaim and regenerate all the filtered HCO_3^-. The daily amount that must be reabsorbed can be calculated by the product of the glomerular filtration rate (GFR) and the HCO_3^- concentration in ECF (180 L/day GFR × 24 mEq/L HCO_3^- = 4,320 mEq/day).[1] The proximal tubule reabsorbs about 85% of the filtered HCO_3^-. The loop of Henle and the distal tubule reabsorb about 10%.[5] Acid salts, such as HPO_4^- (pK_α of 6.8), that have a pK_α greater than the pH of the urine (titratable acids) can accept a proton and be excreted as the acid, thus regenerating an HCO_3^- anion.[5] Sulfuric acid and other acids with a pK_α less than 4.5 are not titratable. Protons from these acids must be combined with another buffer to be secreted. Glutamine deamination in proximal tubular cells forms NH_3, which accepts these protons. In the collecting tubule, the NH_4^+ produced is lipid insoluble, trapping it in the lumen and causing its excretion, eliminating the proton, and allowing for regeneration of HCO_3^-.[4–6] Figure 26-2 is a simplified illustration of the buffering of these acids.

The daily metabolism of carbohydrates and fats generates about 15,000 mmol of CO_2. Although CO_2 is not an acid, it reversibly combines with H_2O to form carbonic acid (i.e., H_2CO_3). Respiration prevents the accumulation of volatile acid through the exhalation of CO_2. Metabolism of proteins and fats results in several fixed acids and bases. Amino acids such as lysine and arginine have a net positive charge and serve as acids. Compounds such as glutamate, aspartate, and citrate have a negative charge. In general, animal proteins contain more sulfur and phosphates, producing an acidic diet. Vegetarian diets consist of more organic anions, resulting in a more alkaline diet.[7] Normally, fatty acids are metabolized to HCO_3^-; however, during starvation or diabetic ketoacidosis, they may be incompletely oxidized to acetoacetate and β-hydroxybutyric acid.[6] The typical diet generates a net nonvolatile acid load of about 70 to 100 mEq of H^+ (1.0–1.5 mEq/kg)/day.[1,8] Renal excretion of 70 mEq in 2 L of urine each day would require a pH of 1.5. Because the kidney cannot produce a pH less than 4.5, most of this fixed acid load must be buffered. The primary buffers for renal net acid excretion are NH_3^-/NH_4^+ and titratable buffers, such as $HPO_4^-/H_2PO_4^{2-}$, as mentioned earlier.[7] The correct assessment of acid–base disorders begins with an evaluation of appropriate laboratory data and an understanding of the physiologic mechanisms responsible for maintaining a normal pH.

Laboratory Assessment

Laboratory data used to evaluate acid–base status are arterial pH, arterial carbon dioxide tension (Paco$_2$), and serum bicarbonate (HCO_3^-).[9–11] These values are obtained routinely with an arterial blood gas (ABG) determination. Acid–base abnormalities occur when the concentration of $Paco_2$ (an acid) or HCO_3^- (a base) is altered. ABG measurements also include the arterial oxygen tension (Pao_2); however, this value does not directly influence decisions regarding acid–base abnormalities. Normal ABG values are listed in Table 26-1. When arterial pH is less than 7.35, the patient is considered acidemic, and the process that caused acid–base imbalance is called acidosis. Conversely, when the arterial pH is greater than 7.45, the patient is considered alkalemic, and the causative process is alkalosis. The process is further defined as respiratory in cases of an inappropriate elevation or depression of $Paco_2$ or metabolic with an inappropriate rise or fall in serum HCO_3^-.

Acid–base balance is normally maintained by the primary extracellular buffer system of HCO_3^-/CO_2. Components of this buffer system are measured routinely to assess acid–base status. Other extracellular buffers (e.g., serum proteins, inorganic phosphates) and intracellular buffers (e.g., hemoglobin, proteins, phosphates), however, also contribute significant buffering activity.[1,7–10] Serum electrolytes are obtained to calculate the anion gap, an estimate of the unmeasured cations and anions in serum. The anion gap helps determine the probable cause of a metabolic acidosis.[6,10,12–21] Urine pH, electrolytes, and osmolality help to further differentiate among the possible causes of metabolic acidosis.[10,22–26]

Acid–Base Balance, Carbon Dioxide Tension, and Respiratory Regulation

In aqueous solution, carbonic acid (i.e., H_2CO_3 formed through the reaction described in Eq. 26-1) reversibly dehydrates to form carbon dioxide (CO_2) and water (H_2O) as shown in Eq. 26-2.

The enzyme carbonic anhydrase (CA), present in red blood cells, renal tubular cells, and other tissues, catalyzes the interconversion of carbonic acid and carbon dioxide. Some of the carbon dioxide produced by dehydration of carbonic acid remains dissolved in plasma, but most exists as a volatile gas:

$$\begin{array}{c} HCO_3^- + H^+ \Leftrightarrow H_2CO_3 \overset{CA}{\Leftrightarrow} CO_2\ (\text{dissolved}) + H_2O \\ \uparrow\downarrow \\ k \times CO_2\ (\text{gas}) \end{array} \qquad \text{(Eq. 26-3)}$$

In Eq. 26-3, k is a solubility constant that has a value of approximately 0.03 in plasma at body temperature.[2,26] Virtually, all the carbonic acid in body fluids is in the form of carbon dioxide. The $Paco_2$, a measure of carbon dioxide gas, is therefore directly proportional to the amount of carbonic acid in the HCO_3^-/H_2CO_3 buffer system. The normal range for $Paco_2$ is 35 to 45 mm Hg.

Table 26-1

Normal Arterial Blood Gas Values

ABGs	Normal Range
pH	7.35–7.45
Pao_2	80–105 mm Hg
$PaCO_2$	35–45 mm Hg
HCO_3^-	22–26 mEq/L

ABG, arterial blood gas.

The lungs can rapidly exhale large quantities of carbon dioxide and thereby contribute significantly to the maintenance of a normal pH. Carbon dioxide formed through the reaction described in Eq. 26-3 diffuses easily from tissues to capillary blood and from pulmonary capillary blood into the alveoli where it is exhaled from the body.[3] Pulmonary ventilation is regulated by peripheral chemoreceptors (located in the carotid arteries and the aorta) and central chemoreceptors (located in the medulla). The peripheral chemoreceptors are activated by arterial acidosis, hypercarbia (elevated $Paco_2$), and hypoxemia (decreased Pao_2). Central chemoreceptors are activated by cerebrospinal fluid (CSF) acidosis and by elevated carbon dioxide tension in the CSF.[3] Activation of these chemoreceptors stimulates the respiratory control center in the medulla to increase the rate and depth of ventilation, which results in increased exhalation of carbon dioxide.

In clinical practice, the serum bicarbonate concentration usually is estimated from the total carbon dioxide content when the serum concentration of electrolytes are ordered on an electrolyte panel or calculated from the pH and $Paco_2$ on an ABG determination. These estimations of the serum bicarbonate concentration are more convenient than directly measuring serum bicarbonate. The total carbon dioxide content that is reported on serum electrolyte panels is determined by acidifying serum to convert all the bicarbonate to carbon dioxide and measuring the partial pressure of CO_2 gas. Approximately 95% of the total carbon dioxide content is bicarbonate. The serum bicarbonate concentration reported on ABG results is calculated from the patient's pH and $Paco_2$ using the Henderson–Hasselbalch equation (Eq. 26-4). This calculated bicarbonate concentration should be within 2 mEq/L of the measured total carbon dioxide. The normal range of serum bicarbonate using these methods is 22 to 26 mEq/L.[10]

$$\mathrm{pH} = \mathrm{pK} + (\mathrm{base})/(\mathrm{acid}) \qquad \text{(Eq. 26-4)}$$

EVALUATION OF ACID–BASE DISORDERS

Acid–base disorders should be evaluated using a stepwise approach.[24,25]

1. Obtain a detailed patient history and clinical assessment.
2. Check the arterial blood gas, sodium, chloride, and HCO_3^-. Identify all abnormalities in pH, $Paco_2$, and HCO_3^-.
3. Determine which abnormalities are primary and which are compensatory based on pH (Table 26-2).

If the pH is less than 7.40, then a respiratory or metabolic acidosis is primary.

If the pH is greater than 7.40, then a respiratory or metabolic alkalosis is primary.

If the pH is normal (7.40) and there are abnormalities in $Paco_2$ and HCO_3^-, a mixed disorder is probably present because metabolic and respiratory compensations rarely return the pH to normal.

4. Always calculate the anion gap. If it is equal to or greater than 20, a clinically important metabolic acidosis is usually present even if the pH is within a normal range.[27]
5. If the anion gap is increased, calculate the excess anion gap (anion gap – 10). Add this value to the HCO_3^- to obtain corrected value.[28]

If the corrected value is greater than 26, a metabolic alkalosis is also present.

If the corrected value is less than 22, a nonanion gap metabolic acidosis is also present.

Table 26-2

Laboratory Values in Simple Acid–Base Disorders

Disorder	Arterial pH	Primary Change	Compensatory Change
Metabolic acidosis	↓	↓HCO_3^-	↓$PaCO_2$
Respiratory acidosis	↓	↑$PaCO_2^-$	↑HCO_3^-
Metabolic alkalosis	↑	↑HCO_3^-	↑$PaCO_2$
Respiratory alkalosis	↑	↓$PaCO_2^-$	↓HCO_3^-

6. Consider other laboratory tests to further differentiate the cause of the disorder.

ı. If the anion gap is normal, consider calculating the urine anion gap.

. If the anion gap is high and a toxic ingestion is expected, calculate an osmolal gap.

If the anion gap is high, measure serum ketones and lactate.

7. Compare the identified disorders to the patient history and begin patient-specific therapy.

METABOLIC ACIDOSIS

Metabolic acidosis is characterized by loss of bicarbonate from the body, decreased acid excretion by the kidney, or increased endogenous acid production. Two categories of simple metabolic acidosis (i.e., normal anion gap and increased anion gap) are listed in Table 26-3. The anion gap (AG) represents the concentration of unmeasured negatively charged substances (anions) in excess of the concentration of unmeasured positively charged substances (cations) in the extracellular fluid. The concentrations of total anions and cations in the body are equal because the body must remain electrically neutral. Most clinical laboratories, however, measure only a portion of these ions (i.e., sodium, chloride [Cl^-], and bicarbonate). The concentrations of other negatively and positively charged substances, such as potassium (K^+), magnesium (Mg^+), calcium (Ca^{2+}), phosphates, and albumin, are measured less often. The concentration of unmeasured anions normally exceeds the concentration of unmeasured cations by 6 to 12 mEq/L, and the anion gap can be calculated as follows:

Table 26-3

Common Causes of Metabolic Acidosis

Normal AG	Elevated AG
Hypokalemic	**Renal Failure**
Diarrhea	**Lactic Acidosis**
Fistulous disease	(see Table 26-4)
Ureteral diversions	**Ketoacidosis**
Type 1 RTA	Starvation
Type 2 RTA	Ethanol
Carbonic anhydrase inhibitors	Diabetes mellitus
Hyperkalemic	**Drug Intoxications**
Hypoaldosteronism	Ethylene glycol
Hydrochloric acid or precursor	Methanol
Type 4 RTA	Salicylates
Potassium-sparing diuretics	
Amiloride	
Spironolactone	
Triamterene	

AG, anion gap; RTA, renal tubular acidosis.

$$\text{Anion gap} = Na^+ - (Cl^- + HCO_3^-) \qquad \text{(Eq. 26-5)}$$

Of the unmeasured anions, albumin is perhaps the most important. In critically ill patients with hypoalbuminemia, the calculated AG should be adjusted using the following formula: adjusted AG = AG + 2.5 × (normal albumin − measured albumin in g/dL), where a normal albumin concentration is assumed to be 4.4 g/dL.[16–19] For example, a hypoalbuminemic patient (serum albumin, 2.4 g/dL) with early sepsis and lactic acidosis might have a calculated AG of 11 mEq/L; however, after the calculation is corrected for the effect of the abnormal serum albumin concentration, the presence of elevated AG acidosis is more prominent (the calculated AG is adjusted: $AG_{(adjusted)}$ = 11 mEq/L + 2.5 × [normal albumin – measured albumin] = 16 mEq/L).

Metabolic acidosis with a normal AG (e.g., hyperchloremic metabolic acidosis) usually is caused by loss of bicarbonate and can be further characterized as hypokalemic or hyperkalemic.[5,23,26,29–36] Diarrhea can result in severe bicarbonate loss and a hyperchloremic metabolic acidosis. Elevated AG metabolic acidosis usually is associated with overproduction of organic acids or with decreased renal elimination of nonvolatile acids.[26,37–39] Increased production of organic acids (e.g., formic, lactic acids) is buffered by extracellular bicarbonate with resultant consumption of bicarbonate and appearance of an unmeasured anion (e.g., formate, lactate).[24,37,38] The decrement in serum bicarbonate approximates the increment in the AG, the latter being a good estimate of the circulating anion level. Prolonged hypoxia results in lactic acidosis. Uncontrolled diabetes mellitus or excessive alcohol intake with starvation can cause ketoacidosis. In the case of renal failure, the capacity for H^+ secretion diminishes, resulting in metabolic acidosis.[29] The accompanying increased AG results from decreased excretion of unmeasured anions such as sulfate and phosphate.[20]

Normal Anion Gap (Hyperchloremic) Metabolic Acidosis

EVALUATION

CASE 26-1

QUESTION 1: J.D., a 21-year-old, 75-kg woman, is hospitalized for evaluation of weakness. She has a history of bipolar affective disorder, pica, and reports recent ingestion of paint from the walls of her house. J.D.'s only current medication is lithium carbonate 300 mg 3 times a day (TID). On admission, she appears weak and apathetic and complains of anorexia. Laboratory tests reveal the following:

Serum Na, 143 mEq/L
K, 3.0 mEq/L
Cl, 121 mEq/L

Albumin, 4.4 g/dL
pH, 7.28
$Paco_2$, 26 mm Hg
HCO_3^-, 12 mEq/L

Urine pH, 5.5

J.D.'s urine pH after an ammonium chloride (NH_4Cl) 0.1 g/kg IV load is less than 5.1. A bicarbonate load of 1 mEq/kg infused intravenously (IV) for 1 hour induces bicarbonaturia (urinary pH, 7.0) and lowers the serum potassium to 2.0 mEq/L. Her blood pH only increased to 7.31. What type of acid–base disorder is present?

Using a stepwise approach, we see that J.D.'s history gives a clue to the cause for her acidosis. The low pH is consistent with a metabolic acidosis because her CO_2 and HCO_3^- are both reduced (Table 26-3). Alterations in pH resulting from a primary change in serum bicarbonate are metabolic acid–base disorders. Specifically, metabolic acidosis is associated with a decrease in serum HCO_3^- and decreased pH, whereas metabolic alkalosis is associated with an increase in serum HCO_3^- and increased pH. In respiratory disorders, the primary change occurs in the $Paco_2$. If J.D. had a decrease in pH and increase in $Paco_2$, a respiratory acidosis would be present. Because J.D. has a low $Paco_2$ and decreased serum HCO_3^-, she has a metabolic acidosis. In most cases of metabolic acidosis or alkalosis, the lungs compensate for the primary change in serum HCO_3^- concentration by increasing or decreasing ventilation. Most stepwise approaches would next suggest the evaluation of whether the decrease in $Paco_2$ of 14 mm Hg for J.D. is consistent with respiratory compensation (Table 26-4). A primary decrease in the serum bicarbonate to a level of 12 mEq/L should result in a compensatory decrease in the $Paco_2$ concentration by 12 to 14 mm Hg (Table 26-4). J.D.'s $Paco_2$ has fallen by 14 mm Hg (normal, 40 mm Hg; current, 26 mm Hg), confirming that normal respiratory compensation has occurred. When values for $Paco_2$ or serum HCO_3^- fall outside of normal compensatory ranges, either a mixed acid–base disorder, inadequate extent of compensation, or inadequate time for compensation should be suspected.

Nomograms, especially ones that are different for acute and chronic disorders, are inherently difficult to memorize, however, and are often not available to the clinician at the point of care. Following the stepwise approach advocated herein will enable clinicians to identify most clinically important disorders without needing to depend on tables or formulas.

Table 26-4

Normal Compensation in Simple Acid–Base Disorders

Disorder	Compensation[a]
Metabolic acidosis	$\downarrow PaCO_2$ (mm Hg) = 1.0–1.2 × HCO_3^- (mEq/L)
Metabolic alkalosis	$\uparrow PaCO_2$ (mm Hg) = 0.5–0.7 × $\uparrow HCO_3^-$ (mEq/L)
Respiratory acidosis	
Acute	$\uparrow HCO_3^-$ (mEq/L) = 0.1 × $\uparrow PaCO_2$ (mm Hg)
Chronic	

	$\uparrow HCO_3^-$ (mEq/L) = 0.4 × $\uparrow PaCO_2$ (mm Hg)
Respiratory alkalosis	
Acute	$\downarrow HCO_3^-$ (mEq/L) = 0.2 × $\downarrow PaCO_2$ (mm Hg)
Chronic	$\downarrow HCO_3^-$ (mEq/L) = 0.4–0.5 × $\downarrow PaCO_2$ (mm Hg)

[a] Based on change from normal HCO_3^- = 24 mEq/L and $PaCO_2$ = 40 mm Hg.

CAUSES

CASE 26-1, QUESTION 2: What are potential causes of metabolic acidosis in J.D.?

Steps 4 to 7 of the stepwise approach in the evaluation of acid–base disorders are used to further determine the cause of the disorder. In patients with metabolic acidosis, calculation of the AG serves as a first step in classifying the metabolic acidosis and provides additional information about conditions that might be responsible. J.D.'s calculated AG is 10 mEq/L (Eq. 26-5). Thus, J.D. has hyperchloremic metabolic acidosis with a normal AG.

The common causes of metabolic acidosis are presented in Table 26-3.[5,10,37] Normal AG metabolic acidosis usually is caused by gastrointestinal loss of bicarbonate (diarrhea, fistulous disease, ureteral diversions); exogenous sources of chloride (normal saline infusions); or altered excretion of hydrogen ions (renal tubular acidosis). J.D. reports a history of both, pica resulting in paint ingestion (perhaps lead-based paint) and chronic use of lithium. Both lead and lithium have been associated with the development of renal tubular acidosis.[23,40]

Renal Tubular Acidosis

CASE 26-1, QUESTION 3: How do the results of NH_4Cl and sodium bicarbonate ($NaHCO_3$) loading help identify the type of renal tubular acidosis in J.D.?

Renal tubular acidosis (RTA) is characterized by defective secretion of hydrogen ion in the renal tubule with essentially normal GFR. Many medical conditions and chemical substances have been associated with RTA.[23,26] The recognized forms are type 1 (distal), type 2 (proximal), and type 4 (distal, hypoaldosterone). Type 1 RTA is caused by a defect in the distal tubule's ability to acidify the urine. The most common causes in adults are autoimmune disorders, toluene sniffing in recreational drug users, and marked volume depletion.[41] Type 2 RTA is caused by altered urinary bicarbonate reabsorption in the proximal tubule as can occur with the use of acetazolamide. Type 4 is characterized by hypoaldosteronism and impaired ammoniagenesis.[23,34]

Evaluation of bicarbonate reabsorption during bicarbonate loading and of response to acid loading by infusion of ammonium chloride is useful in distinguishing among the various types of RTA. In healthy subjects, approximately 10% to 15% of the filtered bicarbonate escapes reabsorption in the proximal tubule, but it is reabsorbed in more distal segments of the nephron. Urine bicarbonate excretion is therefore negligibly small, and urine pH is maintained between 5.5 and 6.5.

Type 2 RTA is associated with a decrease in proximal tubular bicarbonate reabsorption. The distal tubular cells partially compensate for this defect by increasing bicarbonate reabsorption, but urinary bicarbonate excretion still is increased. As occurred with A.B., serum HCO_3^- concentration in patients with type 2 RTA may acutely fall below a threshold of 15 but then stabilize around 15 mEq/L.[10,23] At this point, distal bicarbonate delivery no longer is excessive, allowing the distal nephron to acidify the urine appropriately and excrete acid in the form of titratable ammonia and phosphate.

In type 1 RTA, a defect in net hydrogen ion secretion results from a back-diffusion of H^+ from the tubule lumen to the tubule cell. Patients with type 1 RTA cannot reduce their urine pH below 5.5 even when systemic acidosis is severe.[34]

J.D.'s response to the acid (NH_4Cl) load demonstrates an ability to acidify the urine (i.e., pH < 5.1), which helps rule out type 1 RTA. During bicarbonate loading in patients with type 2 RTA, serum bicarbonate concentration is increased, and abnormally large amounts of bicarbonate are again delivered to the distal tubule. Its hydrogen secretory processes are overwhelmed, resulting in bicarbonaturia. Administration of bicarbonate to J.D. produced bicarbonaturia and an elevation in urine pH (7.0), with low blood pH (7.31). These findings indicate that the reabsorption of bicarbonate in the proximal tubule is impaired, which is characteristic of type 2 RTA. Type 4 RTA is unlikely given her initial serum potassium of 3.0 mEq/L.

Lead-Induced

CASE 26-1, QUESTION 4: What is the cause of J.D.'s proximal RTA?

The most likely cause of A.B.'s proximal RTA is her exposure to presumably lead-based paint. The pathogenesis of lead-induced type 2 RTA is unclear. Some studies suggest that carbonic anhydrase deficiency in the proximal tubule is the major factor, but these data are inconclusive.

CASE 26-1, QUESTION 5: Why is J.D. hypokalemic?

Bicarbonate wasting in proximal RTA is associated with sodium loss, extracellular fluid reduction, and activation of the renin–angiotensin–aldosterone axis. Aldosterone increases distal tubular sodium reabsorption and greatly augments potassium and hydrogen ion secretion. This results in potassium wasting, which explains J.D.'s hypokalemia.[42] When plasma bicarbonate achieves steady state, less bicarbonate reaches the distal tubule, and the stimulus for aldosterone release is removed. Therefore, J.D. experiences only a mild depletion of potassium body stores. When J.D. is exposed to bicarbonate loading, the renin–angiotensin–aldosterone axis is reactivated, and hypokalemia worsens. In addition, raising the concentration of bicarbonate in the blood drives potassium intercellularly and contributes to her hypokalemia.

TREATMENT

CASE 26-1, QUESTION 6: What treatment is indicated for J.D.?

Although it is rare for patients with type 2 RTA to develop severe acidosis and potassium depletion chronically, it is not uncommon in an acute situation such as this. J.D. has a bicarbonate deficit; thus, she should be treated with alkali replacement, and the offending agent, if confirmed to be lead, should be removed concurrently. Her serum potassium is also dangerously low, and bicarbonate correction could further decrease it. J.D. needs potassium supplementation. The clinician should obtain hourly blood samples for electrolytes until her potassium is greater than 3.5 mEq/L. In adults such as J.D., chronic treatment often is not needed because acidosis is self-limited. J.D., however, should be treated with sodium bicarbonate until proximal RTA resolves. Very large doses of bicarbonate (6–10 mEq/kg/day) would be required to increase serum bicarbonate to the normal range.[10] In adults with proximal RTA, however, the goal is to increase serum bicarbonate to no more than 18 mEq/L.[23] Bicarbonate can be provided as sodium bicarbonate tablets (8 mEq/600-mg tablet) or Shohl's solution. Shohl's solution, USP, contains 334 mg citric acid and 500 mg sodium citrate per 5 mL. Sodium citrate is metabolized to sodium bicarbonate in the liver. Shohl's solution provides 1 mEq of sodium and 1 mEq of bicarbonate per milliliter of solution. Therapy for J.D. should be initiated with 1 mEq/kg/day. The clinician should monitor A.B.'s lithium levels while she is receiving alkali therapy. Sodium ingestion might increase renal lithium excretion and exacerbate her bipolar disorder. Because of severe hypokalemia resulting from alkali administration, supplemental potassium as chloride, bicarbonate, acetate, or citrate salts also should be administered.

Metabolic Acidosis with Elevated Anion Gap

EVALUATION AND OSMOLAL GAP

CASE 26-2

QUESTION 1: G.D., a 64-year-old, 60-kg man, is brought to the emergency department (ED) by his family in a semicomatose state. He was found lying on the floor of his garage near a partially empty bottle of windshield wiper fluid 30 minutes ago. G.D. has a long history of alcohol abuse and recently diagnosed dementia. In the

ED, supine blood pressure (BP) is 120/60 mm Hg, pulse is 100 beats/minute, and respiratory rate is 40 breaths/minute. G.D.'s pupils are reactive, and mild papilledema is noted. Laboratory tests reveal the following:

Serum Na, 139 mEq/L
K, 5.8 mEq/L
Cl, 103 mEq/L
Blood urea nitrogen (BUN), 25 mg/dL
Creatinine, 1.4 mg/dL
Fasting glucose, 150 mg/dL

ABG include pH, 7.16; $Paco_2$, 23 mm Hg; and HCO_3^-, 8 mEq/L. His toxicology screen is negative for alcohol, and his serum osmolality is 332 mOsm/kg. What acid–base disturbance is present in G.D., and what are possible causes of the disorder?

G.D. has an acidosis (pH, 7.16; HCO_3^-, 8 mEq/L) with a large AG (28 mEq/L). Subtracting 10 from the anion gap of 28 and adding this value to his serum bicarbonate concentration (see Step 5 in the section Evaluation of Acid–Base Disorders) yields a value of 26, suggesting no other metabolic abnormality is present.

An elevated AG metabolic acidosis often indicates lactic acidosis resulting from intoxications (e.g., salicylates, acetaminophen, methanol, ethylene glycol, paraldehyde, metformin) or ketoacidosis induced by diabetes mellitus, starvation, or alcohol.[14,21,25,38,43–48] Step 6 in the stepwise approach leads to the consideration of additional laboratory tests that may be helpful in the differential diagnosis of an elevated AG. These include serum ketones, glucose, lactate, BUN, creatinine, and plasma osmolal gap.[25] Osmolal gap is defined as the difference between measured serum osmolality (SO) and calculated SO using Eq. 26-6.

$$\begin{aligned}\text{Calculated SO}\,(\text{mOsm}/\text{kg}) = {} & 2 \times \text{Na}^+\,(\text{mEq}/\text{L}) \\ & + \text{Glucose}\,(\text{mg}/\text{dL})/18 \qquad \text{(Eq. 26-6)} \\ & + \text{BUN}\,(\text{mg}/\text{dL})/2.8\end{aligned}$$

When the difference between measured and calculated SO is greater than 10 mOsm/kg, the presence of an unmeasured osmotically active substance, such as ethanol, methanol, or ethylene glycol, should be considered.[25,49] G.D.'s calculated SO is 295 mOsm/kg, compared with the measured value of 332; therefore, his osmolal gap is 37 mOsm/kg. An increase in the anion gap and osmolal gap, without diabetic ketoacidosis or chronic renal failure, suggests the possibility of metabolic acidosis resulting from a toxic ingestion.[25] On the basis of G.D.'s presentation (papilledema, history of alcohol abuse, increased osmolal gap, increased AG metabolic acidosis), history of dementia, and partially empty bottle of windshield wiper fluid found at the scene, methanol intoxication should be considered.

CAUSES

Methanol-Induced

CASE 26-2, QUESTION 2: How would G.D.'s methanol intake induce metabolic acidosis with an elevated anion AG?

Methanol intoxication results in the formation of two organic acids, formic and lactic acids, which consume bicarbonate with production of an AG metabolic acidosis. Alcohol dehydrogenase in the liver metabolizes methanol to formaldehyde and then to formic acid. The formic acid contributes to the metabolic acidosis and also is responsible for the retinal edema and blindness associated with methanol intoxication.[25,26,48]

Serum lactic acid concentrations also are increased in patients with methanol intoxication.[25] Lactic acidosis classically has been divided into type A, which is associated with inadequate delivery of oxygen to the tissue, and type B, which is associated with defective oxygen utilization at the mitochondrial level (Table 26-5). Although these distinctions often are not clear, the lactic acidosis caused by methanol intoxication is most consistent with the type B variety.[50]

TREATMENT

CASE 26-2, QUESTION 3: How should G.D.'s methanol intoxication be managed acutely?

Antidotes

Because G.D.'s mental status is impaired and his respiratory rate is 40 breaths/minute, his airway was secured via endotracheal intubation and he was placed on mechanical ventilatory support. Even though both ethanol and fomepizole compete with methanol for alcohol dehydrogenase binding sites and could be used to treat G.D., fomepizole is chosen because it is easier to dose and does not need serum-level monitoring to ensure efficacy like ethanol.[26,48–52] Because ethanol and fomepizole have much greater affinity for alcohol dehydrogenase than methanol, these agents may reduce the conversion of methanol to its toxic metabolite, formic acid. The unmetabolized methanol is then excreted by the lungs and kidneys. Fomepizole can be given IV as a 15 mg/kg loading dose for 30 minutes, followed by bolus doses of 10 mg/kg every 12 hours. Because of induction of metabolism of fomepizole, doses should be increased to 15 mg/kg every 12 hours if therapy is required beyond 2 days.[48] Fomepizole is usually continued until the serum methanol concentration is less than 20 mg/dL (6.2 mmol/L). Adverse effects of fomepizole are relatively mild; G.D. should be monitored for headache, nausea, dizziness, agitation, metallic taste, abnormal smell, and rash. Cofactor therapy with folinic acid or folic acid at a dosage of 50 mg IV every 6 hours should be given to enhance the elimination of formate along with IV thiamine because of G.D.'s history of chronic alcoholism.

Table 26-5

Common Causes of Lactic Acidosis

Type A	Type B
Anemia	Diabetes mellitus
Carbon monoxide poisoning	Liver failure
Congestive heart failure	Renal failure
Shock	Seizure disorder
Sepsis	Leukemia
	Drugs
	Didanosine
	Ethanol
	Isoniazid
	Metformin
	Methanol
	Salicylates
	Zidovudine

Because of its high cost and infrequent use, some hospitals might not have fomepizole readily available. In such cases, ethanol is an alternative. Administration of IV ethanol as an antidote can be technically difficult and may produce central nervous system (CNS) depression.[48,51] For G.D., an IV-loading dose of 0.6 g/kg ethanol solution should be administered over the course of 30 minutes, followed by a continuous infusion of about 150 mg/kg/hour if the patient has been drinking, or 70 mg/kg/hour for nondrinkers if the patient was not drinking. Serum ethanol concentration should be maintained at more than 100 mg/dL.[26,50] Charcoal may be considered to bind other agents that may be coingested.[26,53]

When other low-molecular-weight toxins, such as ethanol or ethylene glycol, are not present, the serum methanol level can be estimated by multiplying the patient's osmolal gap by a standardized conversion factor of 2.6. G.D.'s osmolal gap of 37 mOsm/L, therefore, may reflect a methanol level of approximately 96 mg/dL (37 mOsm/L × 2.6). When methanol blood levels are higher than 50 mg/dL, hemodialysis is indicated to rapidly reduce concentrations of methanol and its toxic metabolite. The dosage of fomepizole or ethanol should be increased in patients receiving hemodialysis to account for the increased elimination of these antidotes.[26,50] Ethylene glycol poisoning can also be treated by using fomepizole or ethanol.

Bicarbonate

In general, a severe acidosis causes reduced myocardial contractility, impaired response to catecholamines, and impaired oxygen delivery to tissues as a result of

2,3-diphosphoglycerate depletion. For this reason, some clinicians have judiciously administered IV sodium bicarbonate to patients with metabolic acidosis in an attempt to raise the arterial pH to about 7.20.[15,54,55] In G.D.'s case, bicarbonate therapy is indicated in an attempt to raise the pH to 7.3 which converts formic acid (unionized metabolite of methanol) to formate (ionized form) to decrease tissue penetration. If IV sodium bicarbonate is given, the amount required to correct serum HCO_3^- and arterial pH can be estimated using Eq. 26-7 as follows:

$$\begin{aligned}\text{Bicarbonate dose (mEq)} &= 0.5\ (\text{L/kg}) \times \text{Body weight (kg)}\\ &\quad \times \text{Desired increase in serum} \qquad \text{(Eq. 26-7)}\\ &\quad HCO_3^-\ (\text{mEq/L})\end{aligned}$$

Bicarbonate distributes to approximately 50% of total body weight (thus, the factor of 0.5 L/kg in Eq. 26-7). To prevent overtreating, bicarbonate doses should only attempt to increase the bicarbonate concentration by 4 to 8 mEq/L (see Case 26-2, Question 4).[54] For G.D., the dose required to raise serum bicarbonate from 8 to 12 mEq/L amounts to 120 mEq of bicarbonate (0.5 L/kg × 60 kg × 4 mEq/L; Eq. 26-7). Clinical assessment of the effect of bicarbonate can be determined about 30 minutes after administration.[54] Arterial pH and serum bicarbonate concentrations should be obtained before any additional therapy.

RISKS OF BICARBONATE THERAPY

CASE 26-2, QUESTION 4: What are the risks of G.D. bicarbonate therapy?

Concerns about the risks of bicarbonate administration and the failure of studies to demonstrate significant short-term benefits have raised questions about the appropriateness of bicarbonate therapy in metabolic acidosis, particularly in ketoacidosis and lactic acidosis caused by cardiac arrest or other hypoxic events.[55–61] Bicarbonate administration can result in overalkalinization and a paradoxical transient intracellular acidosis. Whereas arterial pH can increase rapidly after bicarbonate administration, intracellular pH increases more slowly because of slow penetration of the negatively charged bicarbonate ion across cell membranes. The bicarbonate in plasma, however, is converted rapidly to carbonic acid, and the carbon dioxide tension increases as a result (Eq. 26-2). Because CO_2 diffuses into cells more rapidly than HCO_3^-, the intracellular HCO_3^-/CO_2 ratio decreases, resulting in a decrease in intracellular pH. This intracellular acidosis will persist as long as bicarbonate administration exceeds the CO_2 excretion; therefore, adequate tissue perfusion and ventilation must be provided in patients with diminished CO_2 excretion (e.g., cardiac or respiratory failure).[56]

Overalkalinization also will cause a shift to the left in the oxygen–hemoglobin dissociation curve. This shift increases hemoglobin affinity for oxygen, decreases oxygen delivery to tissues, and potentially increases lactic acid production and accumulation.[26] Sodium bicarbonate administration also can cause hypernatremia, hyperosmolality, and volume overload; however, the excessive sodium and water retention usually can be avoided by the administration of loop diuretics.[26,49] Hypokalemia is another potential adverse effect of bicarbonate therapy. Acidosis stimulates movement of potassium from intracellular to extracellular fluid in exchange for hydrogen ions. When acidosis is corrected, potassium ions move intracellularly, and hypokalemia can occur. This translocation of potassium tends to reduce serum potassium levels by about 0.4 to 0.6 mEq/L for each 0.1 unit increase in pH, although wide interpatient variability in this relationship exists.[5,8] In G.D. and other patients with organic acid intoxications, raising extracellular pH helps to provide a gradient to shift the toxin from the CNS and "trap" it into the blood and urine, thus enhancing elimination. To prevent the risks of bicarbonate therapy, G.D.'s mental status, serum sodium and potassium levels, and ABG should be monitored.

METABOLIC ALKALOSIS

Metabolic alkalosis is associated with an increase in serum bicarbonate concentration and a compensatory increase in Paco_2 (caused by hypoventilation). The two general classifications of metabolic alkalosis, saline-responsive and saline-resistant (Table 26-6), are usually distinguishable based on an assessment of the patient's volume status, BP, and urinary chloride concentration.

Table 26-6

Classification of Metabolic Alkalosis

Saline-Responsive	Saline-Resistant
Diuretic therapy	Normotensive
Extracellular volume contraction	Potassium depletion
Gastric acid loss	Hypercalcemia
Vomiting	Hypertensive
Nasogastric suction	Mineralocorticoids
Exogenous alkali administration	Hyperaldosteronism
Blood transfusions	Hyperreninism
	Licorice

Saline-responsive metabolic alkalosis is associated with disorders that result in the loss of chloride-rich, bicarbonate-poor fluid from the body (e.g., vomiting, nasogastric suction, diuretic therapy, cystic fibrosis). Physical examination may reveal volume depletion (e.g., orthostatic hypotension, tachycardia, poor skin turgor), and the urinary chloride concentration often will be less than 10 to 20 mEq/L (although urine chloride levels may be >20 mEq/L in patients with recent diuretic use).[10,27,62]

Severe hypokalemia or excessive mineralocorticoid activity can result in a saline-resistant metabolic alkalosis, but this disorder is rare in comparison with saline-responsive metabolic alkalosis. Saline-resistant metabolic alkalosis should be suspected in alkalemic patients with evidence of increased ECF volume, hypertension, or high urinary chloride values (>20 mEq/L) without recent diuretic use.[10,62]

Evaluation

CASE 26-3

QUESTION 1: S.J., a 75-year-old, 60-kg woman, was admitted to the hospital 4 days ago with peripheral edema and pulmonary congestion consistent with a congestive heart failure exacerbation. Since admission, she has been treated aggressively with furosemide 80 to 120 mg IV daily, which has generated approximately 3 L of urine output each day. Today her lung sounds are clear and peripheral edema shows considerable improvement with diuresis; however, she now complains of dizziness when she gets out of bed to go to the bathroom. Physical examination reveals a tachycardic (heart rate [HR], 100 beats/minute), thin elderly woman with poor skin turgor and slight muscle weakness. S.J.'s electrocardiogram shows flattened T waves and U waves. Laboratory tests reveal the following:

Serum Na, 138 mEq/L
K, 2.5 mEq/L
Cl, 92 mEq/L
Creatinine, 0.9 mg/dL
BUN, 28 mg/dL
pH, 7.49
Paco_2, 46 mm Hg
HCO_3^-, 34 mEq/L

Urine Cl concentration is 60 mEq/L. What acid–base disorder is present in S.J.?

Using the stepwise approach to the evaluation of acid–base disorders as previously described, S.J.'s elevated pH is consistent with alkalosis.

Furosemide-induced diuresis may be a clue to her acid–base disorder. The increased serum HCO_3^- and increased Paco_2 suggest primary metabolic alkalosis with respiratory compensation. S.J.'s anion gap is 12, suggesting no additional metabolic acid–base abnormalities are present. A Paco_2 of 46 mm Hg suggests normal respiratory compensation for metabolic alkalosis. Appropriate treatment of the metabolic alkalosis should return her Paco_2 to normal if there is no underlying pulmonary disease.

Causes

DIURETIC-INDUCED

CASE 26-3, QUESTION 2: What is the most likely cause of S.J.'s acid–base imbalance?

Common causes of metabolic alkalosis are listed in Table 26-6. The hypokalemic, hypochloremic, metabolic alkalosis in S.J. most likely is the result of diuretic-induced volume contraction. The incidence of this adverse effect is influenced by the type, dose, and dosing frequency of the diuretic.

Diuretics cause metabolic alkalosis (sometimes referred to as a "contraction alkalosis") by the following mechanisms. First, they enhance excretion of sodium chloride and water, resulting in extracellular volume contraction. Volume contraction alone will cause only a modest increase in plasma bicarbonate; however, volume contraction also stimulates aldosterone release. Aldosterone increases distal tubular sodium reabsorption and induces hydrogen ion and potassium secretion, resulting in alkalosis and hypokalemia. In addition, hypokalemia induced by diuretics will stimulate intracellular movement of hydrogen ions to replace cellular potassium, producing extracellular alkalosis. Hypochloremia also is important in sustaining metabolic alkalosis. In a hypochloremic state, sodium will be reabsorbed, accompanied by bicarbonate generated by secreted hydrogen (Fig. 26-1).[62–64]

Treatment

CASE 26-3, QUESTION 3: How should S.J.'s acid–base imbalance be corrected and monitored?

Treatment of metabolic alkalosis depends on removal of the cause. S.J.'s diuretic therapy should be temporarily discontinued until her volume status and electrolytes can be restored. The initial goal is to correct fluid deficits and replace chloride and potassium by infusing sodium and potassium chloride. As long as hypochloremia exists, renal bicarbonate excretion will not occur and the alkalosis will not be corrected.[63] The severity of alkalosis dictates how rapidly fluid and electrolytes should be administered. In patients with hepatic or renal failure or congestive heart failure, infusion of large volumes of sodium and potassium salts can produce fluid overload or hyperkalemia. Thus, fluid and electrolyte replacement should proceed cautiously, and these patients should be monitored closely for these complications.

Potassium chloride should be administered to correct S.J.'s hypokalemia. The amount of potassium required to replace total body stores is difficult to determine accurately because 98% of the potassium in the body is intracellular. Although wide variation exists, for each 1 mEq/L decrease in K^+ from an ECF concentration of 4 mEq/L, the total body K^+ deficit is about 4 to 5 mEq/kg.[10] S.J.'s serum potassium is 2.5 mEq/L, which correlates with a decrease of about 350 mEq in total body potassium stores. S.J. should be treated with the chloride salt to ensure potassium retention and correction of alkalosis. Potassium replacement can be achieved over the course of several days with supplements of 100 to 150 mEq/day given either orally in divided doses or as a constant IV infusion. S.J.'s laboratory tests for BUN, creatinine, chloride, sodium, and potassium should be monitored during sodium and potassium chloride therapy. As noted earlier, hypercapnia should disappear after correction of the alkalemia, and can be confirmed with an ABG, if clinically indicated.

CASE 26-3, QUESTION 4: What other agents are available to treat S.J.'s alkalosis if fluid and electrolyte replacement does not correct the arterial pH?

Patients unresponsive to sodium and potassium chloride therapy or those at risk for complications with these agents can be treated with acetazolamide, hydrochloric acid (HCl), or a hydrochloric acid precursor. The most commonly used agent is acetazolamide, a carbonic anhydrase inhibitor that blocks hydrogen ion secretion in the renal tubule, resulting in increased excretion of sodium and bicarbonate. Although the serum bicarbonate concentration often improves with acetazolamide, metabolic alkalosis may not completely resolve. Other concerns with the use of acetazolamide include its ability to promote kaliuresis and its relative lack of effect in patients with renal dysfunction.[62,65,66]

A solution of 0.1 N HCl may be administered to patients who require rapid correction of alkalemia. The dose of HCl is based on the bicarbonate excess using Eq. 26-8, where the factor 0.5 × body weight (kg) represents the estimated bicarbonate space.[10,62,63,65]

$$\text{Dose of HCl (mEq)} = 0.5 \times \text{Body weight (kg)} \times (\text{plasma bicarbonate} - 24) \qquad \text{(Eq. 26-8)}$$

Parenteral hydrochloric acid is prepared extemporaneously by adding the appropriate amount of 1 N HCl through a 0.22-μm filter into a glass bottle containing 5% dextrose or normal saline. The dilute solution should be administered through a central venous catheter in the superior vena cava to reduce the risk of extravasation and tissue damage. The infusion rate should not exceed 0.2 mEq/kg/hour.[65] ABG should be monitored at least every 4 hours during the infusion. HCl should not be added to parenteral nutrition solutions.[66]

RESPIRATORY ACIDOSIS

Respiratory acidosis occurs as a result of inadequate ventilation by the lungs. When the lungs do not excrete CO_2 effectively, the Paco$_2$ rises. This elevation in Paco$_2$ (a functional acid) causes a fall in pH (Eq. 26-3). Common causes of respiratory acidosis are listed in Table 26-7. They generally can be categorized into conditions of airway obstruction, reduced stimulus for respiration from the CNS, failure of the heart or lungs, and disorders of the peripheral nerves or skeletal muscles required for ventilation.[67]

Table 26-7

Common Causes of Respiratory Acidosis

Airway Obstruction	**Cardiopulmonary**
Foreign body aspiration	Cardiac arrest
Asthma	Pulmonary edema or infiltration
COPD	Pulmonary embolism
Adrenergic blockers	Pulmonary fibrosis
CNS Disturbances	**Neuromuscular**
Cerebral vascular accident	Amyotrophic lateral sclerosis
Sleep apnea	Guillain–Barré syndrome
Tumor	Myasthenia gravis
CNS depressant drugs	Hypokalemia
Barbiturates	Hypophosphatemia
Benzodiazepines	Drugs
Opioids	Aminoglycosides
	Antiarrhythmics
	Lithium
	Phenytoin

CNS, central nervous system; COPD, chronic obstructive pulmonary disease.

Evaluation

CASE 26-4

QUESTION 1: B.B., a 70-year-old man, is admitted to the hospital for treatment of an exacerbation of chronic obstructive pulmonary disease (COPD). He complains of worsening shortness of breath and increased production of sputum for the past 3 days. He has also noted a mild headache, a flushed feeling, and drowsiness within the past 24 hours. He has a history of COPD, hypertension, coronary artery disease, and low back pain.

Current medications are tiotropium one inhalation daily, salmeterol dry powder inhaler one inhalation BID, chlorthalidone 12.5 mg daily, long-acting diltiazem 240 mg daily, and diazepam 5 mg TID as needed for back pain.

Vital signs include respiratory rate of 16 breaths/minute and HR of 90 beats/minute. Diffuse wheezes and rhonchi are heard on chest auscultation. Laboratory tests reveal the following:

Na, 140 mEq/L
K, 4.0 mEq/L
Cl, 100 mEq/L
pH, 7.32
$Paco_2$, 58 mm Hg
Pao_2, 58 mm Hg
HCO_3^-, 29 mEq/L

B.B.'s baseline ABG at the physician's office last month was pH, 7.35; $Paco_2$, 51 mm Hg; Pao_2, 62 mm Hg; and HCO_3^-, 28 mEq/L. Which of B.B.'s signs and symptoms are consistent with the diagnosis of respiratory acidosis?

A stepwise evaluation reveals a respiratory acidosis. A history of COPD and physical findings of dyspnea, headache, drowsiness, and flushing support the ABG evaluation. Respiratory acidosis also can cause more severe symptoms, including CNS effects, such as disorientation, confusion, delirium, hallucinations, and coma. These CNS abnormalities probably are partly caused by the direct effects of carbon dioxide. Hypoxemia (decreased Pao_2), which commonly accompanies respiratory acidosis, also contributes to these symptoms. Elevated $Paco_2$ causes cerebral vascular dilation, resulting in headache caused by increased blood flow and increased intracranial pressure. Cardiovascular effects typically include tachycardia, arrhythmias, and peripheral vasodilation.[68]

CASE 26-4, QUESTION 2: Is the respiratory acidosis present in B.B. consistent with an acute or a chronic disorder?

Following the stepwise approach, it is determined that B.B. has a respiratory acidosis. He has a normal AG. Comparing his current to previous values (e.g., pH, $Paco_2$, HCO_3^-), it appears B.B. has an acute-on-chronic respiratory acidosis because his baseline $Paco_2$ was 51 mm Hg with an acute worsening to 58 mm Hg. In respiratory acidosis, increased renal reabsorption of bicarbonate compensates for the increase in $Paco_2$; however, at least 48 to 72 hours are needed for this compensatory mechanism to become fully established.[10] Patients with COPD commonly present with an acute-on-chronic respiratory acidosis similar to B.B.

Causes

CASE 26-4, QUESTION 3: What potential causes of respiratory acidosis are present in B.B.?

Respiratory acidosis often is caused by airway obstruction, as shown in Table 26-6.[67,68] Chronic obstructive airway disease is a common cause of both acute and chronic respiratory acidosis. Upper respiratory tract infections, such as acute bronchitis, can worsen airway obstruction and produce acute respiratory acidosis.

DRUG-INDUCED

B.B.'s drug therapy also may be contributing to respiratory insufficiency. Many drugs (Table 26-7) decrease ventilation, but usually these drugs only significantly affect patients who are predisposed to respiratory problems because of underlying diseases. Because B.B. has COPD, he may be more sensitive to drugs affecting respiration. The benzodiazepines, barbiturates, and opioids minimally decrease respiration in normal subjects and in most patients with COPD when given in usual therapeutic doses. These drugs, however, can cause significant respiratory insufficiency when administered either in large doses or in combination with other respiratory depressant drugs.[68] B.B.'s diazepam may be contributing to hypoventilation and respiratory acidosis and should be withdrawn from his regimen. Nonselective adrenergic blocking drugs should be used cautiously in patients with COPD.

Treatment

CASE 26-4, QUESTION 4: How should B.B.'s respiratory acidosis be treated?

As with most cases of respiratory acidosis, treatment primarily involves correction of the underlying cause of respiratory insufficiency. In this case, treatment of acute bronchospasm with a β-adrenergic agent, such as inhaled albuterol, is warranted. Corticosteroids, such as methylprednisolone (60–125 mg every 6–12 hours initially), are commonly used in hospitalized patients with acute exacerbations of COPD.[69] Antibiotic therapy with a β-lactam with or without a β-lactamase inhibitor should be considered in hospitalized patients producing purulent, large-volume secretions.[70] B.B's respiratory status should be monitored closely during his hospitalization. If the acidosis, hypercarbia, or associated hypoxemia worsen, noninvasive positive-pressure ventilation or intubation with mechanical ventilation may be required.[54]

Treatment with IV sodium bicarbonate is not recommended in most cases of acute respiratory acidosis because of the risks associated with bicarbonate therapy (see Case 26-2, Question 4) and because an absolute deficiency of bicarbonate is not present. When the excess CO_2 is excreted, arterial pH should return to normal. Hypercapnia should not be overcorrected, because hypocapnia results in decreased lung compliance, increases dysfunctional surfactant production, and shifts the oxyhemoglobin dissociation curve to the left, restricting the release of oxygen to tissues.[60,61,71]

RESPIRATORY ALKALOSIS

Respiratory alkalosis usually is not a severe disorder. Excessive rate or depth of respiration results in increased excretion of carbon dioxide, a fall in $Paco_2$, and a rise in arterial pH. Common causes of respiratory alkalosis are presented in Table 26-8. Many conditions can cause respiratory alkalosis by stimulating respiratory drive in the CNS. In addition, pulmonary diseases can stimulate receptors in the lung to increase ventilation, and conditions that decrease oxygen delivery to tissues also can stimulate ventilation, causing respiratory alkalosis.[72,73]

Evaluation

CASE 26-5

QUESTION 1: S.P., a 50-year-old, 80-kg woman, is admitted for treatment of presumed bacterial pneumonia. She was in good health until 24 hours before presentation when she noted an abrupt onset of fever, a productive cough with thick, yellowish sputum;

and chest pain on deep inspiration. She has taken aspirin 650 mg every 3 hours since the onset of fever, with mild relief. Since arriving in the ED, she has become anxious and lightheaded and has developed tingling in her hands, feet, and lips. Vital signs include the following: temperature, 38°C; respiratory rate, 24 breaths/minute; HR, 110 beats/minute; and BP, 135/70 mm Hg. Physical examination reveals dullness to percussion, rales, and decreased breath sounds over the left lower lung field.

Laboratory findings include the following:
Serum Na, 135 mEq/L
Cl, 105 mEq/L
pH, 7.49
$Paco_2$, 30 mm Hg
Pao_2, 90 mm Hg
HCO_3^-, 22 mEq/L

Gram stain of sputum reveals 25 white blood cells per high-power field and many gram-positive diplococci. White blood cell count is 15,400 cells/μL with a left shift. A left lower lobe infiltrate is seen on chest radiograph. What acid–base disorder is present in S.P.?

Steps 1 to 3 in the evaluation of the ABG values, as described previously, indicate a respiratory alkalosis (increased pH, decreased $Paco_2$). The history and physical findings of deep, rapid breathing and tingling sensations are clues to the etiology.

This disorder is most likely acute because her HCO_3^- concentration is normal. She does not have an AG. If a large AG were present, it would suggest she has a coexisting metabolic acidosis, possibly caused by salicylate intoxication (see Case 26-5, Question 3).

CASE 26-5, QUESTION 2: Which of S.P.'s signs and symptoms are consistent with the diagnosis of acute respiratory alkalosis?

S.P.'s paresthesias of the extremities and perioral region, lightheadedness, tachycardia, and increased rate and depth of respiration are common signs and symptoms of respiratory alkalosis. Confusion and decreased mental acuity also may be evident.[5,6,10] Simple respiratory alkalosis rarely produces life-threatening abnormalities.

Causes

CASE 26-5, QUESTION 3: What is the cause of the acid–base disorder in S.P.?

Table 26-8

Common Causes of Respiratory Alkalosis

CNS Disturbances	**Pulmonary**
Bacteremia	Pneumonia
Cerebrovascular accident	Pulmonary edema
Fever	Pulmonary embolus
Hepatic cirrhosis	
Hyperventilation	**Tissue Hypoxia**
Anxiety-induced	High altitude
Voluntary	Hypotension
Meningitis	CHF
Pregnancy	
Trauma	**Other**
Drugs	Excessive mechanical ventilation
Progesterone derivatives	Rapid correction of metabolic acidosis
Respiratory stimulants	
Salicylate overdose	

CHF, congestive heart failure; CNS, central nervous system.

Common causes of respiratory alkalosis are listed in Table 26-8.[5,6,10,72–74] Based on physical examination, laboratory findings, and chest radiograph, S.P. appears to have an acute bacterial pneumonia. Pneumonia and other pulmonary diseases can result in stimulation of ventilation and respiratory alkalosis, even with a normal Pao_2, as in this case. The anxiety S.P. is experiencing also may be contributing to respiratory alkalosis by producing the familiar anxiety–hyperventilation syndrome. Although salicylate intoxication is a potential cause of respiratory alkalosis because of the direct respiratory stimulant effect of salicylate,[74] S.P. displays few other symptoms of salicylate intoxication (e.g., nausea, vomiting, tinnitus, altered mental status, elevated AG metabolic acidosis). The total aspirin dose reportedly ingested (65 mg/kg in 24 hours) is not large enough to be associated with significant risk for toxicity.

Treatment

CASE 26-5, QUESTION 4: What is the appropriate treatment for S.P.'s respiratory alkalosis?

Similar to respiratory acidosis, treatment of respiratory alkalosis usually involves correcting the underlying disorder. Initiation of appropriate antibiotic therapy for a community-acquired pneumonia is indicated in this case (see Chapter 67, Respiratory Tract Infections). Simple respiratory alkalosis is unlikely to cause life-threatening symptoms, although mortality rates for critically ill patients with this disorder can be high.[68] The well-known remedy of rebreathing expired air from a paper bag for treatment of hyperventilation associated with anxiety appears to be effective for this cause of respiratory alkalosis and may be helpful for S.P.

MIXED ACID–BASE DISORDERS

Evaluation

CASE 26-6

QUESTION 1: B.L., a 65-year-old man who was transferred from a long-term acute care facility 2 days previously, is disorientated and lethargic. He was doing well until 1 week before admission, when the staff noted that he was somnolent. He progressively became more lethargic and could no longer remember the names of other persons. B.L. has a history of alcoholic cirrhosis, type 2 diabetes mellitus, and hypertension. Medications before admission were nadolol 80 mg daily, isosorbide mononitrate 20 mg BID, glyburide 10 mg daily, and spironolactone 50 mg BID. On admission, B.L. was disoriented to person, place, and time and was difficult to arouse. Vital signs include the following: temperature, 37°C; respirations, 16 breaths/minute; HR, 70 beats/minute; and BP, 154/92 mm Hg. Physical examination revealed asterixis and mild ascites. Laboratory studies included the following:

Na, 133 mEq/L	Albumin, 3.2 g/dL
K, 4.3 mEq/L	Ammonia, 120 μmol/L
Cl, 106 mEq/L	pH, 7.43
BUN, 5 mg/dL	$Paco_2$, 30 mm Hg
Creatinine, 0.7 mg/dL	Pao_2, 90 mm Hg
Fasting glucose, 150 mg/dL	HCO_3^-, 19 mEq/L

On admission, spironolactone was increased to 200 mg daily and lactulose 60 mL orally QID was started for treatment of hepatic encephalopathy. Within the first 24 hours of lactulose therapy, B.L. produced four loose, watery stools; however, his mental status worsened to the point of being unresponsive, his BP dropped to 100/60 mm Hg, and his breathing became labored and eventually required mechanical ventilation. At the time of intubation, his laboratory values were as follows:

Na, 137 mEq/L	Arterial pH, 7.06
K, 4.5 mEq/L	Paco_2, 48 mm Hg
Cl, 105 mEq/L	Pao_2, 58 mm Hg
BUN, 10 mg/dL	HCO_3^-, 13 mEq/L
Creatinine, 1.2 mg/dL	

Gram stain of peritoneal fluid revealed many WBC and gram-negative rods; the diagnosis of spontaneous bacterial peritonitis with septic shock is made. Describe B.L.'s acid–base status on admission and at the current time.

An evaluation of B.L.'s first ABG results using Steps 1 and 2 (in the section Evaluation of Acid–Base Disorders) reveals abnormal Paco_2 and serum bicarbonate values, suggesting the existence of an underlying acid–base abnormality. The direction of change in his Paco_2 and serum HCO_3^-, along with a pH of 7.43, suggests a respiratory alkalosis is the primary disorder. His calculated AG of 8 is not increased. Examination of the ranges of expected compensation in Table 26-3 reveals that these values are indeed consistent with chronic respiratory alkalosis (serum HCO_3^- decreased by 0.5 mEq/L for each 1 mm Hg drop in Paco_2). B.L.'s history of alcohol-induced liver disease is consistent with the diagnosis of chronic respiratory alkalosis (Table 26-8).[8,10]

The second set of ABG reveals severe acidosis. B.L.'s serum bicarbonate has fallen from 19 to 13 mEq/L, and his Paco_2 has increased acutely from 30 to 48 mm Hg. Because these values have changed in opposite directions, a mixed acid–base abnormality should be suspected.

The diagnosis of a mixed metabolic and respiratory acidosis can be confirmed by applying the stepwise approach outlined previously. If the acidosis were purely metabolic in nature, a serum HCO_3^- of 13 mEq/L should result in hyperventilation and a low Paco_2. B.L.'s Paco_2 of 48 mm Hg is high, which would be consistent with coexistent respiratory acidosis. The anion gap is 19, indicating an AG metabolic acidosis is present. The excess AG (AG – 10 = 9) added to B.L's HCO_3^- of 13 yields a corrected HCO_3^- of 22, which is normal. This suggests no additional metabolic disturbances are present.

Causes

CASE 26-6, QUESTION 2: What are possible causes for the mixed acidosis in B.L.?

The AG should be calculated in all patients with a metabolic acidosis. B.L.'s calculated AG has increased from 8 to 19 mEq/L (11 and 22 mEq/L, respectively, after adjusting for hypoalbuminemia), suggesting that an elevated AG acidosis is now present. Septic shock from bacterial peritonitis can produce profound hypotension, which leads to tissue hypoperfusion, generation of lactic acid, and a subsequent elevation in the AG. Other causes of elevated AG metabolic acidosis can be excluded with additional laboratory data (e.g., serum ketones, glucose, osmolal gap).

Although diarrhea and spironolactone should be considered in the differential diagnosis, these are usually associated with hyperchloremic, normal AG metabolic acidosis (Table 26-2).[75] The coexisting respiratory acidosis is most likely the result of B.L.'s altered mental status and his diminished respiratory drive.

CASE 26-6, QUESTION 3: During the next 6 hours, B.L.'s hepatic encephalopathy, peritonitis, and acid–base disorders are aggressively treated with lactulose, antibiotics, fluids, and mechanical ventilation. His most recent ABG reveals the following:

pH, 7.45
Paco_2, 24 mm Hg
Pao_2, 90 mm Hg
HCO_3^-, 16 mEq/L

Ventilator settings are assist-control mode at 16 breaths/minute, tidal volume 700 mL, and inspired oxygen concentration 40%. B.L. is noted to be more awake, anxious, and initiating 25 to 30 breaths/minute. What is the current acid–base status and probable cause?

Evaluation of the ABG reveals a pH at the upper limit of normal with significant decreases in both Paco_2 and serum HCO_3^- concentration. This clinical scenario is most consistent with a mixed acute respiratory alkalosis and ongoing metabolic acidosis. The time frame in which B.L.'s Paco_2 decreased from 48 to 24 mm Hg is consistent with acute respiratory alkalosis. B.L.'s low serum HCO_3^- suggests ongoing metabolic acidosis as a result of his septicemia. The metabolic acidosis should improve with time, given adequate antibiotic therapy and supportive measures that maintain BP and increase oxygen delivery to the tissues.

The acute respiratory alkalosis in this case is most likely caused by the mechanical ventilator, B.L.'s anxiety, or sepsis. In the assist-control mode, any inspiratory effort by B.L. results in the delivery of a fully assisted breath by the ventilator.[76] B.L.'s anxiety and resultant tachypnea are resulting in over ventilation, producing excessive CO_2 elimination and respiratory alkalosis. Appropriate changes in the therapy may include use of an anxiolytic, an analgesic if needed to treat pain, changing the ventilator settings, or probably a combination of these strategies.

Fluid and Electrolyte Disorders

Alan H. Lau and Priscilla P. How

CORE PRINCIPLES

		CHAPTER CASES
	FLUID AND SODIUM DISORDERS	
1	Plasma osmolality is maintained within normal limits through a delicate balance between water intake and excretion. Antidiuretic hormone (ADH) plays an important role in maintaining fluid balance in the body.	**Case 27-1 (Question 1), Figure 27-1**
2	Signs of volume depletion include orthostatic hypotension, dry mucous membranes, and poor skin turgor. Because water and sodium are inherently linked, the assessment of volume status and selection of replacement fluid require examination of sodium concentration.	**Case 27-2 (Questions 1, 2)**
3	Aldosterone is the main regulatory hormone for sodium homeostasis. A patient may have hypotonic, isotonic, or hypertonic hyponatremia depending on the plasma osmolality. Normal serum sodium concentration is 135–145 mEq/L.	**Cases 27-4 through 27-7, Figure 27-1**
4	Hypovolemic hypotonic hyponatremia can occur with volume depletion and decreased extracellular fluid. Calculation of sodium deficit will determine how much sodium replacement is required.	**Case 27-5 (Questions 1, 2)**
5	Hypervolemic, hypotonic hyponatremia is caused by a disproportionate accumulation of ingested water relative to sodium. It is also observed in patients with heart failure, liver and renal failure, and nephrotic syndrome. Management includes sodium and water restriction, as well as the use of diuretics.	**Case 27-6 (Question 1)**
6	Syndrome of inappropriate antidiuretic hormone is a common cause of normovolemic hypotonic hyponatremia. Persistent ADH secretion together with water ingestion results in hyponatremia.	**Case 27-7 (Question 1)**
7	Neurologic symptoms may be manifested in acute or severe hyponatremia. Low plasma osmolality causes water to move into the brain resulting in cerebral edema, increased intracranial pressure, and central nervous system symptoms. Rapid or overly aggressive correction of hyponatremia can result in osmotic demyelination.	**Case 27-7 (Questions 3, 4)**
	POTASSIUM DISORDERS	
1	The sodium–potassium adenosine triphosphatase pump plays a pivotal role in maintaining potassium homeostasis. Normal serum potassium	**Case 27-8 (Questions 1, 2)**

	concentration is 3.5–5.0 mEq/L. Clinical manifestations of hypokalemia include muscle weakness and electrocardiography (ECG) changes.	
2	Potassium repletion should be guided by close monitoring of serum potassium. Oral supplementation is usually preferred. Patients who cannot tolerate oral potassium or who have severe/symptomatic hypokalemia can receive intravenous potassium. In general, the rate of potassium infusion should not exceed 10 mEq/hour to prevent phlebitis.	**Case 27-8 (Question 3)**

3	Hyperkalemia can be caused by chronic kidney disease and medications that inhibit the renin–angiotensin–aldosterone system. Intravenous calcium is administered to antagonize the cardiac effects (ECG changes and ventricular arrhythmias) of hyperkalemia. Other treatment strategies include the use of insulin and glucose, β_2-agonists, sodium polystyrene sulfonate, sodium bicarbonate, and dialysis.	**Case 27-9 (Question 1), Case 27-10 (Questions 1, 2), Table 27-3**

CALCIUM DISORDERS

1	Normal serum calcium is 8.5–10.5 mg/dL (corrected for serum albumin as calcium is protein-bound). Hypercalcemia can be caused by dehydration, malignancy, hyperparathyroidism, vitamin D intoxication, sarcoidosis, and other granulomatous disease. Clinical presentation of hypercalcemia includes signs and symptoms involving the neurologic, cardiovascular, pulmonary, renal, gastrointestinal, and musculoskeletal systems. First-line treatment for hypercalcemia is hydration and diuresis. Calcitonin and bisphosphonates are alternative agents used in the management of hypercalcemia.	**Case 27-11 (Questions 1–3), Table 27-4**

PHOSPHATE DISORDERS

1	Hypophosphatemia can develop as a result of impaired intestinal phosphorus absorption, increased renal elimination, or shift of phosphorus from extracellular to intracellular compartments. Normal serum phosphorus concentration is 2.7–4.7 mg/dL.	**Case 27-12 (Questions 1, 2)**
2	Clinical effects of hypophosphatemia can involve multiple organ systems and are attributed to impaired cellular energy stores and tissue hypoxia secondary to ATP depletion. Phosphorus supplementation can be administered orally or intravenously, depending on the signs and symptoms, and severity of hypophosphatemia. Renal function, serum phosphorus, calcium, and magnesium need to be monitored closely. Diarrhea is a common dose-related side effect of oral phosphorus replacement.	**Case 27-12 (Questions 3, 4)**

MAGNESIUM DISORDERS

1	Magnesium depletion (normal serum magnesium, 1.8–2.4 mEq/L) can result in abnormal function of the neurologic, neuromuscular, and cardiovascular systems. Typical findings include Chvostek and Trousseau signs, muscle fasciculation, tremors, muscle spasticity,	**Case 27-13 (Questions 1, 2)**

	convulsions, and possibly tetany. As serum magnesium does not reflect total body stores, symptoms are more important determinants of the urgency and aggressiveness of magnesium replacement.	
②	Oral magnesium replacement is indicated in asymptomatic patients with mild depletion. Urinary excretion of magnesium increases during intravenous replacement. Thus, replenishment of magnesium stores usually takes several days. After intravenous magnesium administration, the patient should be monitored for hypotension, marked suppression of deep tendon reflexes, ECG and respiration changes, as well as hypermagnesemia.	**Case 27-13 (Questions 3, 4)**
③	A common cause of hypermagnesemia is the use of magnesium-containing laxatives and antacids by patients with renal impairment. Potentially life-threatening complications of severe hypermagnesemia include respiratory paralysis, hypotension, and complete heart block. Intravenous calcium should be administered to antagonize the respiratory and cardiac manifestations of magnesium. Diuretics may be given to patients with good renal function to enhance urinary magnesium excretion.	**Case 27-14 (Questions 1–3)**

BASIC PRINCIPLES

Body Water Compartments and Electrolyte Composition

In newborns, approximately 75% to 85% of body weight is water. After puberty, the percentage of water per kilogram of weight decreases as the amount of adipose tissue increases with age.[1,2] Body water constitutes 50% to 60% of the lean body weight (LBW) in adult men but only 45% to 55% in women because of their greater proportion of adipose tissue. The water content per kilogram of body weight further decreases with advanced age. Total body water (TBW) is usually calculated as 0.6 × LBW in men and 0.5 × LBW in women.

Two-thirds of the total body water resides in the cells (intracellular water). The extracellular water can be divided into different compartments—the interstitial fluid (12% LBW) and the plasma (5% LBW) are the two major compartments. Other compartments of the extracellular fluid (ECF) include the connective tissues and bone water, the transcellular fluids (e.g., glandular secretions), and other fluids in sequestered spaces, such as the cerebrospinal fluid.[1]

The electrolyte composition differs between the intracellular and extracellular compartments. Potassium, magnesium, and phosphate are the major ions in the intracellular compartment, whereas sodium, chloride, and bicarbonate are predominant in the extracellular space.[2] Water travels freely across the cell membranes of most parts of the body. The cell membrane, however, is only selectively permeable to solutes. The impermeable solutes are osmotically active and can exert an osmotic pressure that dictates the distribution of water between fluid compartments. Water moves across the cell membrane from a region of low osmolality to one of high osmolality. Net water movement ceases when osmotic equilibrium occurs. Each fluid compartment contains a major osmotically active solute: potassium in the intracellular space and sodium in the ECF. The volumes of the two compartments reflect the asymmetrically larger number of solute particles or osmoles inside the cells.[2,3]

The capillary wall separates the interstitial fluid from plasma. Because sodium moves freely across the capillary wall, its concentration is identical across both sides of the wall. Therefore, no osmotic gradient is generated, and water distribution between these two spaces is not affected. Plasma proteins, which are confined in the vascular space, are the primary osmoles that affect water distribution between the interstitium and the plasma.[2] In contrast, urea, which traverses both the capillary walls and most cell membranes, is osmotically inactive.[2,3]

Plasma Osmolality

Osmolality is defined as the number of particles per kilogram of water (mOsm/kg). It is determined by the number of particles in solution and not by particle size or valence. Nondissociable solutes, such as glucose and albumin, generate 1 mOsm/mmol of particles; and dissociable salts, such as sodium chloride, liberate two ions in solution to produce 2 mOsm/mmol of salt. The osmolality of body fluid is maintained between 280 and 295 mOsm/kg. Because all body fluid compartments are iso-osmotic, plasma osmolality reflects the osmolality of total body water. Plasma osmolality can be measured by the freezing point depression method, or estimated by the following equation, which takes into account the osmotic effect of sodium, glucose, and urea[2,3]:

$$\begin{aligned} P_{\text{osm}} = {} & 2(\text{Na})(\text{mmol/L}) + \text{Glucose (mg/dL)}/18 \\ & + \text{BUN (mg/dL)}/2.8 \end{aligned} \tag{Eq. 27-1}$$

This equation predicts the measured plasma osmolality within 5 to 10 mOsm/kg. Although urea contributes to the measured osmolality, it is an ineffective osmole because it readily traverses cell membranes and, therefore, does not cause significant fluid shift within the body. Hence, the effective plasma osmolality (synonymous with tonicity, the portion of total osmolality that has the potential to induce transmembrane water movement) can be estimated by the following equation:

$$P_{\text{osm}} = 2(\text{Na})(\text{mmol/L}) + \text{Glucose (mg/dL)}/18 \tag{Eq. 27-2}$$

An osmolal gap exists when the measured and calculated values differ by greater than 10 mOsm/kg[4]; it signifies the presence of unidentified particles. When the individual solute has been identified, its contribution to the measured osmolality can be estimated by dividing its concentration (mg/dL) by one-tenth of its molecular weight. Calculating the osmolal gap is used to detect the presence of substances, such as ethanol, methanol, and ethylene glycol, that have high osmolality. Occasionally, the osmolal gap can also result from an artificial decrease in the serum sodium secondary to severe hyperlipidemia or hyperproteinemia.

CASE 27-1

QUESTION 1: J.F., a 31-year-old man, is admitted to the inpatient medicine service for methanol intoxication. Routine laboratory analysis reveals the following:

Sodium (Na), 145 mEq/L
Potassium (K), 3.4 mEq/L
Blood urea nitrogen (BUN), 10 mg/dL
Creatinine, 1.1 mg/dL
Glucose, 90 mg/dL

The blood methanol concentration was 108 mg/dL, and the measured plasma osmolality was 333 mOsm/kg. What is J.F.'s calculated osmolality? Are other unidentified osmoles present?

Using Equation 27-1, J.F.'s total calculated osmolality is

$$\begin{aligned} P_{osm} &= 2(145\ \text{mEq/L}) + 90\ \text{mg/dL}/18 + 10\ \text{mg/dL}/2.8 \\ &= 290 + 5 + 3.6 \\ &= 299\ \text{mOsm/kg} \end{aligned} \qquad \text{(Eq. 27-3)}$$

$$\text{Osmolal gap} = 333\ \text{mOsm/kg} - 299\ \text{mOsm/kg} = 34\ \text{mOsm/kg} \qquad \text{(Eq. 27-4)}$$

In J.F., the entire osmolal gap can be accounted for by the presence of the methanol (because 108 mg/dL of methanol will provide 108/3.2 = 33.7 mOsm/kg). It is unlikely, therefore, that other unmeasured osmoles are present (e.g., ethylene glycol, isopropanol, and ethanol). The laboratory determination of osmolality measures the total number of osmotically active particles but not their permeability across the cell membrane. Methanol increases plasma osmolality but not tonicity because the cell membrane is permeable to methanol. Therefore, no net water shift occurs between the intracellular and extracellular compartments. Conversely, mannitol, which is confined to the extracellular space, contributes to both plasma osmolality and tonicity.

Tubular Function of Nephron

The kidney plays an important role in maintaining a constant extracellular environment by regulating the excretion of water and various electrolytes. The volume and composition of fluid filtered across the glomerulus are modified as the fluid passes through the tubules of the nephron.

The renal tubule is composed of a series of segments with heterogeneous structures and functions: the proximal tubule, the medullary and cortical thick ascending limb of Henle's loop, the distal convoluted tubule, and the cortical and medullary collecting duct[2] (Fig. 27-1). The mechanism for sodium reabsorption is different for each nephron segment, but it is generally mediated by carrier proteins or channels located on the luminal membrane of the tubule cell.[2] Na^+/K^+ ATPase (sodium–potassium adenosine triphosphatase) actively pumps sodium out of the renal tubule cell in exchange for potassium in a 3:2 ratio. Hence, the intracellular sodium concentration is kept at a low level. The potassium that is pumped into the cell leaks back out through potassium channels in the membrane, rendering the cell interior electronegative. The low intracellular sodium concentration and a negative intracellular potential produce a favorable gradient for passive sodium entry into the cell.[3] Na^+/K^+ ATPase also indirectly provides the energy for active sodium transport and the reabsorption and secretion of other solutes across the luminal membrane of the renal tubule. The distal segments are mainly involved in the reabsorption of sodium and chloride ions and the secretion of hydrogen and potassium ions.[2]

Figure 27-1 Sites of tubule salt and water absorption. Sodium is reabsorbed with inorganic anions, amino acids, and glucose in the proximal tubule against an electrical gradient that is lumen-negative. In the distal part of the proximal tubule (pars recta), sodium and water are reabsorbed to a lesser extent and organic acids (hippurate, urate) and urea are secreted into the urine. The electrical potential is lumen-positive in the pars recta. Water, but not salt, is removed from tubule fluid in the thin descending limb of Henle's loop, but in the ascending portion salt is reabsorbed without water, rendering the tubule fluid hyposmotic with respect to the interstitium. Sodium, chloride, and potassium are reabsorbed by the medullary and cortical portions of the ascending limb; the lumen potential is positive. Sodium is reabsorbed and potassium and hydrogen ions are secreted in the distal tubule and collecting ducts. Water absorption in these segments is regulated by antidiuretic hormone (ADH). The electrical potential is lumen-negative in the cortical sections and positive in the medullary segments. Urea is concentrated in the interstitium of the medulla and assists in the generation of maximally concentrated urine. (Reprinted with permission from Chonko AM et al. Treatment of edema states. In: Narins RG, ed. Maxwell & Kleeman's Clinical Disorders of Fluid and Electrolyte Metabolism. 5th ed. New York, NY: McGraw-Hill; 1994:545.)

Iso-osmotic reabsorption of the glomerular filtrate occurs in the proximal tubule such that two-thirds of the filtered sodium and water and 90% of the filtered bicarbonate are reabsorbed. The Na^+/H^+ antiporter (exchanger) in the luminal membrane is instrumental in the reabsorption of sodium chloride, sodium bicarbonate, and water. The reabsorption of most nonelectrolyte solutes, such as glucose, amino acids, and phosphates, are coupled to sodium transport.[2,5]

Both the thick ascending limb of Henle's loop and the distal convoluted tubule serve as the diluting segments of the nephron because they are impermeable to water.

Sodium chloride is extracted from the filtrate without water. Sodium transport in both of these segments is flow-dependent and varies with the amount of sodium ions delivered from the proximal segments of the nephron. Decreased sodium ions in the tubular fluid will limit sodium transport in the thick ascending limb of Henle's loop and the distal convoluted tubule.[2,6]

Reabsorption of sodium in the thick ascending limb of Henle's loop accounts for approximately 25% of the total sodium reabsorption. Sodium, chloride, and potassium are reabsorbed by the medullary and cortical portions of the ascending limb, but the leakage of reabsorbed potassium ions back into the tubular lumen, via potassium channels, makes the tubular lumen electropositive. This electrical gradient promotes the passive reabsorption of cations, such as sodium, calcium, and magnesium, in the distal convoluted tubules. Because the thick ascending limb of Henle's loop is impermeable to water, it contributes to the interstitial osmolality in the medulla. This high osmolality is key to the reabsorption of water by the medullary portion of the collecting duct under the influence of antidiuretic hormone (ADH, vasopressin). Therefore, the thick ascending limb of Henle's loop is important for both urinary concentration and dilution.[6]

Because, as noted previously, the distal convoluted tubule is also impermeable to water, the osmolality of the filtrate continues to decline as sodium is being reabsorbed. In the distal convoluted tubule and collecting duct, sodium is reabsorbed in exchange for hydrogen ions and potassium. When sodium ions are reabsorbed, the tubule lumen becomes electronegative, which promotes potassium secretion in the lumen via potassium channels. Aldosterone enhances sodium reabsorption in the collecting duct by increasing the number of opened sodium channels.[2,7]

The collecting duct is usually impermeable to water. Under the influence of ADH, however, water permeability is increased through an increase in the number of water channels along the luminal membrane. The amount of water reabsorbed depends on the tonicity of the medullary interstitium, which is determined by the sodium reabsorbed in the thick ascending limb of Henle's loop and urea.[2,7,8]

Osmoregulation

A reduction of intracellular volume often increases effective plasma osmolality; conversely, decreased effective plasma osmolality is associated with cellular hydration. Water homeostasis is important in the regulation of plasma osmolality, and plasma tonicity is maintained within normal limits through a delicate balance between the rates of water intake and excretion.

The amount of daily water intake includes the volume of water ingested (sensible intake), the water content of ingested food, and the metabolic production of water (insensible intake).[2] To maintain homeostasis, these should be equal to the amount of water excreted by the kidney and the gastrointestinal (GI) tract (sensible loss) plus water lost from the skin and respiratory tract (insensible loss).[2,3]

Changes in plasma tonicity are detected by osmoreceptors in the hypothalamus, which also houses the thirst center and is the site for ADH synthesis.[9,10] When the plasma tonicity falls below 280 mOsm/kg as a result of water ingestion, ADH release is inhibited,[2] water is no longer reabsorbed in the collecting duct, and a large volume of dilute urine is excreted. Conversely, when the osmoreceptors in the hypothalamus sense an increased plasma osmolality, ADH is released to increase water reabsorption. A small volume of concentrated urine is then excreted. The threshold for ADH release is 280 mOsm/kg, and maximal ADH secretion occurs when the plasma osmolality is 295 mOsm/kg.[9] Thus, urine osmolality varies from 50 mOsm/kg in the absence of ADH to 1,200 mOsm/kg during maximal ADH release. The volume of urine produced depends on the solute load to be excreted, as well as the urine osmolality[2,3,9,10]:

$$\text{Urine volume (L)} = (\text{Solute load (mOsm)}/\text{Urine osmolality (mOsm/kg)}) \times (1/\text{Density of water (kg/L)}) \qquad \text{(Eq. 27-5)}$$

Therefore, for a typical daily solute load of 600 mOsm:

$$= (600\ \text{mOsm}/50\ \text{mOsm/kg})(1/1\ \text{kg/L}) = 12\ \text{L (No ADH)} \qquad \text{(Eq. 27-6)}$$

$$= (600\ \text{mOsm}/1{,}200\ \text{mOsm/kg})(1/1\ \text{kg/L}) = 0.5\ \text{L (Max ADH)} \qquad \text{(Eq. 27-7)}$$

Although the kidney has a remarkable ability to excrete free water, it is not as efficient in conserving water. ADH minimizes further water loss, but it cannot correct water deficits. Therefore, optimal osmoregulation requires increased water intake stimulated by thirst. Both ADH and thirst can be stimulated by nonosmotic stimuli. For example, volume depletion is such a strong nonosmotic stimulus for ADH release that it can override the response to changes in plasma osmolality. Nausea, pain, and hypoxia are also potent stimuli for ADH secretion.[11]

Volume Regulation

Sodium resides almost exclusively in the ECF; the amount of total body sodium, therefore, determines the extracellular volume.[2,11] Because daily sodium intake varies from 100 to 250 mEq, the body must rely on adjustments in urinary sodium excretion to maintain the extracellular volume and tissue perfusion.[2,11] The ability of the kidney to retain sodium is so remarkable that a person can survive with a daily sodium intake of as low as 20 to 30 mEq.

The afferent sensors for the changes in the effective circulating volume are the intrathoracic volume receptors, the baroreceptors in the carotid sinus and aortic arch, and the afferent arteriole in the glomerulus.[11]

When the effective circulating volume is decreased, both the renin–angiotensin–aldosterone and the sympathetic nervous systems are activated.[2,11] Angiotensin type 2 (AT_2) and norepinephrine enhance sodium reabsorption at the proximal convoluted tubule. In addition, aldosterone stimulates sodium reabsorption at the collecting tubule. The decrease in effective arterial volume also stimulates ADH release, which enhances water reabsorption at the collecting duct. Conversely, after a salt load, the increases in atrial pressure and renal perfusion pressure suppress the production of renin and, subsequently, AT_2 and aldosterone. The release of atrial natriuretic peptide secondary to increased atrial filling pressure and intrarenal production of urodilators increase urinary excretion of the excess sodium.[12,13]

Although the kidney can excrete a 20-mL/kg water load in 4 hours, only 50% of the excess sodium is excreted in the first day.[3] Sodium excretion continues to increase until a new steady state is reached after 3 to 4 days, when intake equals output.[3,12] It is important to recognize that osmoregulation and volume regulation occur independently of each other.[2,3] The two homeostatic systems regulate different parameters and possess different sensors and effectors. Both systems can be activated simultaneously, however.

DISORDERS IN VOLUME REGULATION

Sodium Depletion

CASE 27-2

QUESTION 1: A.B., a 17-year-old girl, presented to the emergency department (ED) with complaints of anorexia, nausea, vomiting, and generalized weakness for the past 3 days. She denied other medical problems and had not used any medications. On examination, her supine blood pressure (BP) was 105/70 mm Hg, with a pulse of 80 beats/minute. Her standing BP was 85/60 mm Hg with a pulse of 100 beats/minute, and she complained of feeling dizzy when she stood up. Her mucous membranes were dry, but her skin turgor was normal. The jugular vein was flat, and peripheral or sacral edema was not present. Laboratory blood tests showed the following:

Serum Na, 134 mEq/L
K, 3.5 mEq/L
Chloride (Cl), 95 mEq/L
Total CO_2 content, 35 mEq/L
BUN, 18 mg/dL
Creatinine, 0.8 mg/dL

Glucose, 70 mg/dL

Random urinary sodium was 40 mEq/L, potassium was 40 mEq/L, and chloride was less than 15 mEq/L. The hemoglobin was 14 g/dL, and white cell and platelet counts were normal. Based on the clinical and laboratory data in A.B., what is the most probable explanation for her presentation?

The signs and symptoms in A.B. are consistent with volume depletion. The loss of gastric fluid owing to vomiting and decreased oral intake secondary to anorexia led to moderate-to-severe volume depletion. She exhibits orthostatic changes in both her BP (a drop in systolic BP of 20 mm Hg) and pulse (an increase of 20 beats/minute). The dry mucous membranes, the flat jugular vein, and the absence of edema support volume depletion as well, and dizziness on standing indicates extracellular volume depletion.[14] Her hypochloremic metabolic alkalosis was probably initiated by loss of acidic gastric contents through vomiting. Her volume depletion increased renal bicarbonate reabsorption, perpetuating the metabolic alkalosis. The decreased renal perfusion brought about by volume depletion enhanced proximal

---

tubular reabsorption of urea, resulting in an increased BUN to creatinine ratio (prerenal azotemia). When renal perfusion is decreased and the renin–angiotensin–aldosterone system is activated, the proximal reabsorption of sodium and chloride is increased. A.B.'s urinary sodium is, therefore, less than 10 mEq/L.[15] Excretion of the poorly permeable bicarbonate ions, however, results in obligatory urinary sodium loss to maintain luminal electroneutrality. A.B.'s urinary sodium was therefore elevated (40 mEq/L). In this situation, the urinary chloride remained low, and this is a better index of volume status.[15] Both urinary sodium and chloride are elevated, however, in patients using diuretics, in those undergoing osmotic diuresis, and in those with underlying renal disease or hypoaldosteronism, even in the face of volume depletion. Physical examination should therefore be conducted as part of the volume status assessment. A.B.'s volume depletion increased the concentration of red blood cells, which could explain her slightly elevated hemoglobin concentration of 14 g/dL.

CASE 27-2, QUESTION 2: How should A.B.'s volume depletion be managed?

The etiology of A.B.'s vomiting should be sought and the cause removed. Because the patient is neither hypernatremic nor hyponatremic, normal saline should be administered intravenously to replenish the extracellular volume and improve tissue perfusion.[2,14] If the patient is hypernatremic (having a greater deficit of water than solute), half-isotonic saline or dextrose solution, which contains more free water, should be administered. In contrast, hyponatremic hypovolemic patients have a greater deficit of solute than water; isotonic or hypertonic saline should then be given. The amount of volume deficit is often difficult to ascertain. Because A.B. was severely orthostatic, 1 or 2 L of fluid can be given over the course of 2 to 4 hours. The subsequent rate of infusion will depend on A.B.'s response and the prevailing symptoms. The clinician should monitor her body weight, skin turgor, supine and upright BP, jugular venous pressure, urine output, and urine chloride concentration to assess the adequacy of volume repletion. Because the treatment goal is to achieve a positive fluid balance, the infusion rate should be 50 or 100 mL/hour in excess of the sum of urine output, insensible losses, and other losses, such as emesis and diarrhea.[2]

Sodium Excess

CASE 27-3

QUESTION 1: L.J., a 45-year-old man, presented to the clinic with complaints of swollen legs and puffy eyelids. He also noticed that his urine had been foamy recently. On examination, his BP was 180/100 mm Hg and his pulse was 80 beats/minute. Bilateral periorbital edema and 2+ bilateral pitting edema up to the thigh were noted. On auscultation, his heart was normal and his lungs had bilateral crackles. His jugular venous pressure was elevated at 10 cm H_2O. Laboratory tests revealed the following:

Serum Na, 132 mEq/L
K, 3.8 mEq/L
Cl, 100 mEq/L
Bicarbonate, 26 mEq/L
BUN, 40 mg/dL
Creatinine, 2.5 mg/dL
Glucose, 120 mg/dL
Albumin, 2 g/dL
Serum cholesterol, 280 mg/dL,
Triglycerides, 300 mg/dL

The serum transaminases, alkaline phosphatase, and bilirubin were within normal limits. Urinalysis showed the following:

Specific gravity, 1.015
pH, 7.0
Protein, >300 mg/dL
24-hour urinary protein excretion, 6 g
Creatinine clearance (CrCl), 40 mL/minute

Urinalysis also showed oval fat bodies and fatty casts. L.J. was taking no medications and he denied illicit drug use. Hepatitis B serology and human immunodeficiency virus (HIV) antibody were negative. The impression was anasarca (total body edema) secondary to nephrotic syndrome. What is nephrotic syndrome? What could be the cause of L.J.'s sodium excess state?

Nephrotic syndrome is characterized by hypoalbuminemia, urine protein excretion greater than 3.5 g/day, hyperlipidemia, lipiduria, and edema.[16,17] The heavy proteinuria is a result of damage to the selective barrier of the glomerulus. The causes of nephrotic syndrome are multiple and diverse.[16] The causes can be idiopathic (primary glomerular disease) or secondary to chronic systemic diseases (e.g., diabetes mellitus, amyloidosis, sickle cell anemia,[18] lupus), cancer (e.g., multiple myeloma, Hodgkin disease), infections (e.g., HIV,[19] hepatitis B, syphilis, malaria), intravenous (IV) drug abuse, and medications (e.g., gold, penicillamine, captopril, nonsteroidal anti-inflammatory drugs [NSAIDs][20]).

A heavy urinary protein loss results in various extrarenal complications.[16,17] Hypoalbuminemia reduces plasma oncotic pressure and contributes to the increased hepatic synthesis of both albumin and lipoproteins. This, coupled with the decreased catabolism of lipoproteins, resulted in L.J.'s hyperlipidemia.[16,21] Urinary loss of inhibitors of coagulation predispose these patients to thromboembolism.[16]

Specific therapy of nephrotic syndrome ranges from simple removal of the offending medication and treatment of the underlying comorbidities to the use of immunosuppressive agents in specific glomerular diseases.

L.J.'s anasarca results from changes in both capillary hemodynamics and renal sodium and water retention.[22] The hypoalbuminemia (2 g/dL) and proteinuria (>300 mg/dL) produce an imbalance in the Starling forces across the capillary wall, namely the hydrostatic and oncotic pressures in the capillary and interstitial compartments. The reduced capillary oncotic pressure favors movement of fluid from the vascular space into the interstitium.[23] This leads to contraction of the effective arterial blood volume, which in turn activates humoral, neural, and hemodynamic mechanisms that signal the kidney to retain sodium and water.[24,25] This underfill hypothesis has been challenged by data, suggesting that hypoalbuminemia plays a minor role in nephrotic edema[26,27] and the observation that patients with nephrotic syndrome can have increased, normal, or decreased plasma volumes.[23]

A defect in the intrarenal sodium handling mechanism that causes inappropriate sodium retention also contributes to nephrotic edema.[23,26] According to this overflow hypothesis, proteinuric renal disease leads to increased sodium reabsorption in the distal nephron. The mechanism is not well defined but may be related to cellular resistance to atrial natriuretic peptide.[23] Thus, a sodium excess state occurs and edema results. It is likely that the interaction between the underfill and overflow mechanisms results in the production of nephrotic edema.[28] Patients with severe hypoalbuminemia (i.e., serum albumin level < 1.5 g/dL), who have a severe reduction in plasma oncotic pressure, are most likely to exhibit evidence of the underfill phenomenon.[22]

CASE 27-3, QUESTION 2: How should L.J.'s sodium excess state be managed?
